***Abstract*—The collection of sensor data and its analysis have become more important as more smart buildings equipped with various sensors are developed. The interconnection of the wire cable through the sensors is indispensable for information collections - such as temperature, humidity, and luminance in the rooms and hallways - and the effective management of the in-building energies. However, these interconnections through the cabling are very costly, time-consuming, and high risky since they can cause some damage to the buildings. Therefore, interconnections through unwired connections are required to ensure the deployment effectiveness such as time and cost. In this paper, the design and short sequence operation appropriateness are confirmed through the simulation of a signal measurement system for in-building propagation characteristics based on short signature sequences, and the analysis of the system characteristics based on the false alarm probability are performed thereafter.**

Keywords—Signal measurement, In-building propagation characteristics, Short signature sequence, In-Building measurement

I. INTRODUCTION

This study designs a measurement system for in-building propagation characteristics and analyzes theses in-building propagation characteristics. Since the in-building propagation characteristics can vary according to the applied building materials and structures, a management system based on these characteristics is needed to develop a management system for smart buildings. To solve such engineering measurement problems, we designed and verified a reference signal generator and a system that measures and analyzes the message quality based on a short sequence according to the propagation characteristics between a transmitter and a receiver. The system operation was checked through a simulation for verifying the design validity and the in-building propagation characteristics were analyzed in the actual indoor environment. Thus, this may contribute to the exploration of the potential for a one-hop network configuration in buildings. In this respect, the propagation characteristics were analyzed and extracted from the data measured by a short-sequence system. An integrated hierarchy system was also designed to measure the in-building propagation characteristics and verified through a simulation. Based on this verified system, a one-way system that collects and analyzes actual measurement data was configured. In other words, it is necessary in an environment with noise and interference to define a short signature sequence so as to easily confirm propagation characteristics and facilitate the actual characteristics' measurement. Through this system design, more practical data may be collected than actual measurements, and thus, the measured environments may be analyzed more closely. Compared with the conventional systems [4] – [5], the proposed system can measure the indoor signal propagation characteristics more reliably due to the signature sequence based measurement procedure.

II. A SHORT-SEQUENCE SYSTEM CONFIGURATION AND ITS VERIFICATION THROUGH A SIMULATION

An in-building propagation environment refers to a setting in which signal paths are surrounded by external walls and structures and the interior of a building is separated by the corridors. The propagation environment can vary according to the basic structures of stepped and corridor buildings. The basic configuration includes the selection of proper frequency bands, choice of the signature sequence, data transfer rate and the modulation method, collection and analysis of the data and transmission power, and estimation of a proper transmitter location

A. An in-building propagation characteristics measurement system based on a short signature sequence

A distinguishable short signature sequence needs to be properly configured so as to measure the in-building propagation characteristics. This sequence should have the basic features of being easily generated and producing a number of signature sequences. In this respect, a basic pattern block needs to be developed and a certain pattern is required to be defined to confirm it even though the quality of the channel can be degraded by interference and noise. In this study, the QPSK (quadrature phase shift keying), a pattern is converted

into bit streams and a relatively high bandwidth utilization and higher order modulation through further improvement can be achieved, was applied. An RRC (root raised cosine) filter was also used to create waveforms in order to minimize the bandwidth for the channel transmission of signals from the binary I and Q channels which were generated by the two bit streams. The waveforms comprise samples of 43 taps. The measurement systems can basically work either in master or in slave mode. The master mode starts with the transmission of signature sequence without conflicts. The measuring system that will receive the signature sequence entirely will participate in the channel evaluation process by working in slave mode. The Figure 1 shows the working process of the measuring system in master mode. As shown in Figure 1, the system in master mode transmits signature sequences for measurement, gives channel numbers to them, and then collects the information of the channels to be measured at the moment. When echo back signature sequences stand by for reception and the signatures are not received normally in the slave system, retransmission procedures and timer motions are controlled. In turn, when the signatures are received normally, it transmits feedback signature sequences again, and then waits for a re-reception of echo back signatures. When the echo back signatures are not received, it delays for a certain period of time, and then transmits the feedback signature sequence again. After such procedures, channels statuses are recorded and the qualities of two-way channels are measured and collected. In the system in slave mode, the motion process is carried out as indicated in Figure 2. When the measuring system receives the signature sequence with a new channel number, it immediately enters the slave mode and then carries out a reception procedure. As shown in Figure 2, when a new signature sequence is received, a new channel number is given and then an echo back signature is transmitted. Also, it stays at the status of feedback signature receiving queue from the master mode, and whether it is received normally or not is checked up. When it is not received normally until the timer ends up, the delay timer is increased and the echo back signature sequence is transmitted again. Likewise, the qualities of new channels can be measured by measuring the delayed values that are continuously received. As indicated above, when quality evaluations of channels are carried out from the continuously received signature sequences and closing messages are received, the measurement process of the channels concerned is finished.

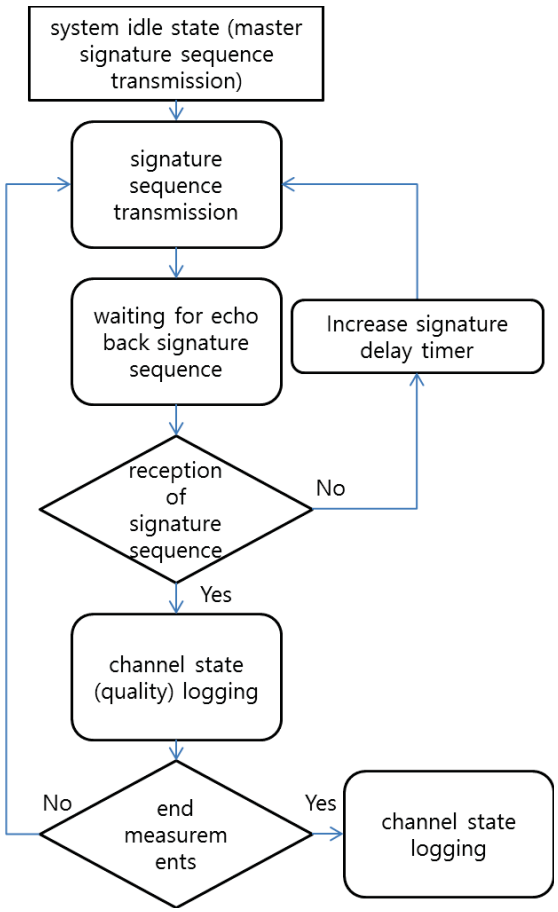

Fig. 1. Operation procedure of the measurement system [Master]

A frame structure of the system produced using the Simulink model based on Matlab is presented in Figure 2 below. After a signature sequence is selected and the transmitting end treatment is complete, the signals are transmitted to the channels. In this study, it is assumed that the noise generated in the channels at this stage is an additive white Gaussian noise (AWGN) [1].

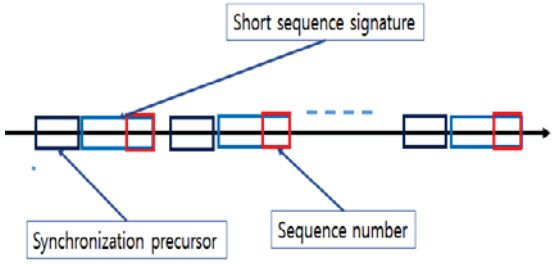

Fig. 2. Frame structure of the short signature sequence system

B. Simulation results and analysis

For the synchronization of the starting point of a frame to the message pattern, a 13-bit Barker sequence, a

synchronization precursor, was used as a basic structure of the signature sequence used in this system as presented in Figure 2. At the receiving end, the correlation value with respect to the synchronization sequence was calculated, and then, the starting point was identified. The optimum time was chosen using the 2 times over-sampled sample streams through the symbol synchronization algorithm. The correlation value was calculated from the synchronized sample with the sequence from the module which generates the Barker sequence (the sample of the QPSK demodulated I and Q channels). The highest correlation value obtained in this stage indicates the starting point of the frame. The parameters for the main system and the signal transmission band are presented in Table 1. The transfer rate can be determined according to the bandwidth available for transmitting the sensor data. When measuring the in-building propagation characteristics, the variable signature sequence (L = 12, 16, 20, 24, 28, etc.), which allows the determination of whether the signal was properly received at the measuring point, needs to be produced and then the treatment is required on the receiving point.

Table 1. Simulation parameters

Parameters	Value
Carrier Frequency	450 MHz
Bandwidth	100 kHz
Modulation	QPSK
Waveform	Raised Cosine Pulse
Message	Signature Sequence
Bit Rate	500 kbps
Oversampling rate	4
Channel Model	In-Building, AWGN

The signature sequences for classifying the different signals ar e respectively mapped to the data bits of the I and Q channels and synthesized with the QPSK modulating signals. As these s ignals are mapped to the intermediate frequency and become t he band passing signals, the frequency shift corresponding to t he RF signals occurs and then the propagation of these signals takes place in the inside of the building. Since the obtained sig nals have a wide frequency bandwidth of square waveforms, p ulse shaping is required to efficiently use the frequency band. I n terms of filters, the present study used the RRC purse shapin g filter with 41 taps [2]-[3].

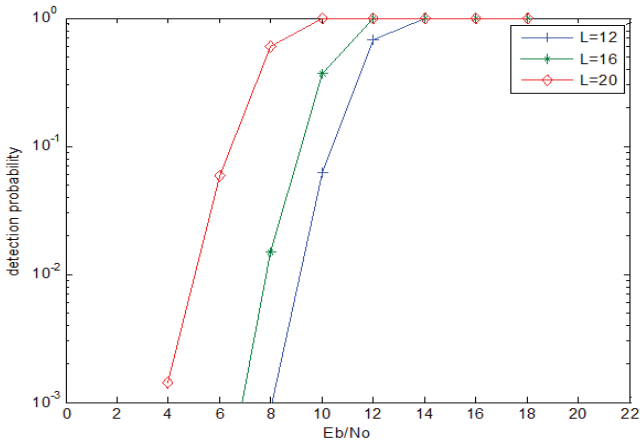

Fig. 3. Detection probability for the short signature sequence with FA = 0.01, L = 12, 16, 20

Since the RRC pulse shaping filter was used at both the transmitting and receiving ends, the signal transmission system without ISI (inter-symbol interference) can be applied. Through the simulation, it was found that when applying the RRC filter at the receiving end, no or minimal ISI can be attained and the bandwidth efficiency and the ISI minimization can be simultaneously achieved. Figure 3 shows the signal detection performances for each signal power when a variable short signature sequence is used and the false alarm probability is one percent. It suggests that a low power is required to get the same detection performances as the lengths of the signature sequence increase.

III. AN ANALYSIS OF THE PERFORMANCE CHARACTERISTICS OF THE SYSTEM

The detection threshold according to the given false alarm probability, power, and length of the short signature sequence is presented in Figure 4. As shown in the figure, as the length of the signature sequence decreases, the detection threshold needs to be higher. This is because the requirements for maintaining the given false alarm probability can be met with the higher detection threshold.

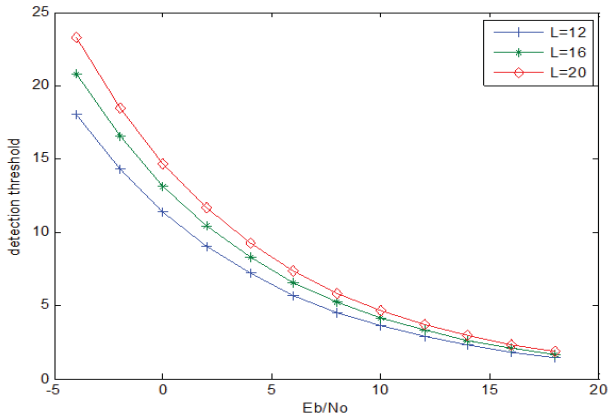

Fig. 4. Detection threshold with FA=0.01, L=12, 16, 20

Figure 5 shows the signal detection performances for each sig nal power when a variable short signature sequence of L = 12, 16, 20 is used and the false alarm probability is 5 percent.

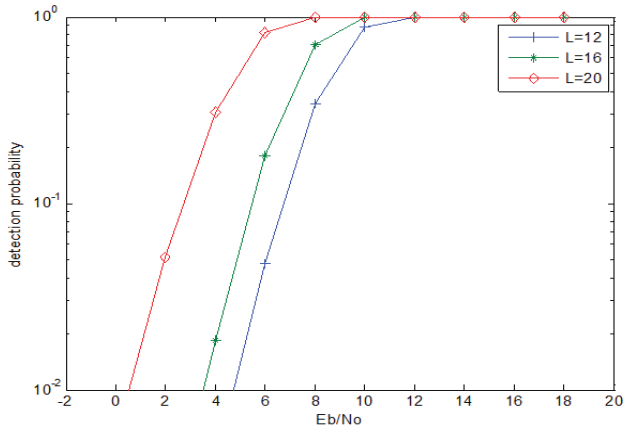

Fig.5. Detection probability for the short signature sequence with FA = 0.05, L = 12, 16, 20

IV. Conclusion

For the actual measurement of real buildings, the present study designed the measurement system based on the short signature sequence to measure the in-building propagation characteristics, produced the thresholds for the signal detection, and analyzed the detection performances. To facilitate the identification of the propagation characteristics in the indoor environment with noise and interference, the short signature sequence was defined, and thus, the practical measurement could be conducted. The identified propagation characteristics through this measurement system may contribute to the efficient configuration of an in-building smart sensor network and the accumulation of various design data. Also, a new algorithm for the two- and three-way signal transmission and reception needs to be applied so as to more efficiently measure and analyze signals.

***Abstract*—User scheduling for downlink channel of multiple-input multiple-output orthogonal frequency-division multiplexing (MIMO-OFDM) system is studied in this paper. By utilizing the channel state information (CSI), base station (BS) selects set of users with best conditioned channel to receive data packets transmitted by transmit antennas to achieve the maximum throughput of the system. MIMO-OFDM system incurs more feedback load compared to that of single carrier MIMO systems. As the feedback load increases with number of subcarriers, per-chunk user scheduling is implemented where adjacent subcarriers are grouped together to reduce the feedback load. Signal-to-interference-plus-noise ratio (SINR) feedback model is considered in this paper for closed-loop MIMO-OFDM. A comparative study of different schemes for achievable net throughput with and without per-chunk user scheduling is carried out. Simulation results for various scenarios are presented and discussed in detail.**

***Index Terms*—MIMO-OFDM user scheduling, SINR Feedback, Per-chunk user scheduling.**

I. Introduction

Higher throughput is required for future wireless communication systems as the demand for broadband wireless services is increasing day by day. Multiple-input multiple-output (MIMO) system increases spectral efficiency of wireless channel in the presence of rich scattering and multipath fading environments [1]–[3]. Foschini *et al.* [4] presented the system capacity analysis for MIMO channels, which helped in suggesting practical structures for obtaining high spectral efficiency. This leads to the architecture called as Bell Laboratories layered space-time (BLAST) and to space-time codes discussed in [5], [6].

It has shown in [2], [3] that the system capacity of point-to-point (single user) MIMO wireless communication link increases linearly by a factor $min\{M, N\}$, where M is the number of transmit antennas at base station (BS) and N is the number of receive antennas at each user terminal (UT). Recently, multiuser MIMO (MU-MIMO) systems become more popular as this transmission strategy achieves more capacity gains in multiuser environment due to a selection diversity technique known as multiuser diversity (MUD) [7], [8].

Caire *et al.* [8] has shown that the Shannon's fundamental sum capacity limit of the MU-MIMO for broadcast channel (BC) is achieved by dirty paper coding (DPC) by serving multiple users equal to the number of transmit antennas at BS simultaneously. The encoding order of the users at BS plays a vital role in DPC as this is an interference pre-subtraction technique and it is required that the decoding order at the receiver to be the reverse order of encoding sequence at transmitter. The search space required for DPC to have the optimal precoding matrices (transmit covariance matrices) is huge. Furthermore, for implementation process of DPC, full noncausal knowledge of the interference signals of users encoded earlier are required for the users other than the first encoded user. This requirement is not practically feasible for real-time systems. Therefore, suboptimal MU-MIMO scheduling schemes with limited channel state information at transmitter (CSIT) have gathered attention as practically feasible alternatives to DPC [9]–[13]. In recent past, soft computing techniques are also used for scheduling [14], [15].

Orthogonal frequency division multiplexing (OFDM) is a technique implemented for multiuser broadcast communication over frequency-selective fading channels as its implementation is relatively less complex. Due to the combined advantages of MIMO and OFDM techniques, MIMO-OFDM is used at the background of modern wireless standards for achieving high capacity communications like LTE (Long Term Evolution) of Third-Generation Partnership Project (3GPP), WiMAX (Worldwide Interoperability for Microwave Access / IEEE 802.16e) etc..

In MU MIMO, BS schedules the best conditioned users to achieve more sum-rate. This needs to be done for each subcarrier present in MU MIMO-OFDM system to have the maximum system throughput. This kind of per-subcarrier resource allocation and scheduling is discussed in [16]. Here, each subcarrier is modulated by the data of the users selected for the corresponding subcarrier. No inter-carrier interference exists because of the orthogonality of the subcarriers. The data rate of the subcarriers are increased by exploiting spatial multiplexing by eigenbeamforming, where parallel spatial channels are created [17]. The feedback load due to MIMO-OFDM is more compared to that of MIMO as multiple subcarriers are present in MIMO-OFDM. Hence, to decrease the feedback load Pun *et al.* [18] introduced the concept of grouping of adjacent subcarriers into clusters. Due to clustering of adjacent subcarriers, the feedback load reduced significantly as compared with per-subcarrier eigenbeamforming but at the cost of system throughput. Eslami et al. in [19] discussed about grouping of adjacent subcarriers into chunks and evaluated the optimum chunk size for maximization of the net throughput for MIMO-OFDM system. It has been shown in [19] that the achievable system sum-rate obtained by chunk concept increases with user size while for other strategies it decrease

to zero.

In this paper, we calculated the system throughput of MU MIMO-OFDM system assuming a closed-loop where each user feeds back the scalar quality of the channel in terms of signal-to-interference-plus-noise ratio (SINR). Here, we evaluated three limited feedback scheduling schemes based on SINR feedback for MU MIMO-OFDM system. To reduce the feedback overhead, we have also implemented per-chunk user scheduling with these sub-optimal scheduling schemes. A comparison of feedback load incurred by these schemes is also presented.

Section II discusses about the system model considered in this paper. Three limited feedback schemes based on SINR feedback model is evaluated for MU MIMO-OFDM system in Section III. The expression for system throughput obtained by user scheduling considering grouping of adjacent subcarriers for multiuser MIMO-OFDM broadcast channel is discussed. Finally, we presented our conclusive remarks in Section IV.

II. System Model

A multiuser MIMO-OFDM broadcast cellular system is considered in this paper. The cellular system consists of a BS with M number of transmit antennas providing services to K geographically dispersed users. Each user has N number of receive antennas. A frequency selective wireless broadcast channel is assumed and this is modelled as a finite impulse response (FIR) filter of length P as discussed in [20]. The MIMO-OFDM channel bandwidth is divided into L orthogonal subcarriers. The received signal received by kth user on the lth subcarrier can be expressed as:

$$\mathbf{Y}_l^k = \mathbf{H}_l^k \mathbf{X}_l + \mathbf{W}_l^k, l = 1, \ldots, L, \tag{1}$$

where $\mathbf{Y}_l^k$ is an $N \times 1$ vector of the received signal at the user k on the lth subcarrier, $\mathbf{X}_l$ is an $M \times 1$ vector of the transmitted signal on the subcarrier l, and $\mathbf{W}_l^k$ is an $N \times 1$ vector of additive noise whose individual entries are independent and identically distributed (i.i.d) complex Gaussian with zero mean and unit variance. i.e., $\mathcal{CN}(0,1)$. $\mathbf{H}_l^k$ is an $N \times M$ matrix known as channel matrix and (n,m)th entry h_l^k(n,m) $\sim \mathcal{CN}(0,1)$ is i.i.d $\mathcal{CN}(0,1)$. Each element of this channel matrix is the complex channel gain coefficient from transmit antenna m to receive antenna n of user k on the lth subcarrier. The lth tone of the kth user's space frequency channel, $\mathbf{H}_l^k$ can be described as:

$$\mathbf{H}_l^k = \sum_{p=0}^{P-1} \sigma_p \mathbf{F}[k,p] exp\left(-j2\pi \frac{l}{L} p\right), 0 \le l \le L-1, \tag{2}$$

where exp(.) represents the exponential function, $\mathbf{F}[k,p]$ is an $M \times M$ square matrix $\forall p \in \{0, \ldots, P\}$. The channel impulse response of kth user is represented by $\mathbf{F}[k,p]$. Independent elements of $CN(0,1)$ are present in each element of $\mathbf{F}$. Further,we assume that these matrices are mutually uncorrelated. σ^2 for $p = 0, \ldots, P-1$ represents the channel power delay profile normalized by assuming $\sum_{p=0}^{P-1} \sigma_p^2 = 1$. The power delay profile of the frequency selective wireless channel is represented by $\sigma^2 \forall p \in \{0, \ldots, P\}$. The condition needs to be satisfied is $\sum_{p=0}^{P-1} \sigma_p^2 = 1$. The wireless channel characteristics do not change for one coherence time period, i.e., the channel is assumed to be quasi-static in nature as discussed in [19]. As $\mathbf{W}_l^k$ is the normalized noise vector, the average SNR is equal to ρ which defines the power constraint at BS as $\rho = (1/L) \sum_{l=0}^{L-1} Tr\left(\mathbf{E}[\mathbf{X}_l \mathbf{X}_l^H]\right)$.
The received signal at the nth receive antenna of the kth user on the lth subcarrier can be expressed as :

$$y_l^k(n) = \sum_{m=1}^{M} h_l^k(n,m) x_l(m) + w_l^k(n), \tag{3}$$

where the transmitted signal from transmit antenna m on the lth subcarrier is $x_l(m)$, the additive white Gaussian noise for nth receive antenna of the kth user on the lth subcarrier is $w_l^k(n)$.

The signal received by the user from the desired transmit antenna on the lth subcarrier is treated as the desired signal. The interference for the user comprises of the signals received from the transmit antennas other than the desired one on the subcarrier l. Let the signal $x_l(m)$ is the desired signal for the kth user and the interference signals for kth user are $x_l(m'), m' \neq m$ on the lth subcarrier. Then, the *instantaneous* SINR for $y_l^k(n)$ can be expressed as:

$$SINR_l^k(m,n) = \frac{|h_l^k(n,m)|^2}{\frac{M}{\rho_k} + \sum_{m' \neq m} |h_l^k(n,m')|^2}, \tag{4}$$

where ρ_k is the average signa-to-noise ratio (SNR) of user k. In this paper, we consider the homogeneous network, where all the users experience the same SNR, i.e., $\rho_k = \rho$ for $k = 1, \ldots, K$. We use sum-rate and throughput interchangeably throughout this paper.

III. Limited Feedback Schemes for MU MIMO-OFDM

Here, FDM is considered for per-subcarrier scheduling, i.e., the scheduling schemes are implemented for each subcarrier individually. The computation of achievable system throughput can be expressed as below:

$$T \le E\left[\frac{1}{L} \sum_{l=1}^{L} T_l\right]. \tag{5}$$

and T_l can be computed similar to [9]

$$T_l^k \le E\left[\sum_{m=1}^{M} \log_2(1 + \max_{n \in \{1,\ldots,N\}, k \in U} SINR_l^k(m,n)\right], \tag{6}$$

where $E[x]$ is the mathematical expectation value of x and U is the set of M number of users selected for receiving the data for the BS. The instantaneous throughput of the antenna selection with the feedback of SINR value can be expressed as in [10] :

$$T_l^k = \sum_{m=1}^{M} \log_2(1 + \max_{n \in \{1,\ldots,N\}, k \in U} SINR_l^k(m,n)). \tag{7}$$

We consider the below mentioned three sub-optimal feedback scheduling algorithms for closed-loop MIMO-OFDM broadcast network.

A. Limited Feedback Scheduling: Scheme I

First, each user calculates all the possible SINR values depending on all possible combinations of transmit antenna and receive antenna for a subcarrier. Then, each user selects the maximum among them and feeds back the maximum SINR value along with the index of the transmit antenna corresponding to that SINR value to BS. At BS, after receiving all the feedback data from all the users, the BS selects the users having the largest SINR values corresponding to each transmit antenna. Then after scheduling is done at BS, BS transmits the mutually independent data to the set of users scheduled for each transmit antenna as discussed in [10]. This process should be repeated for all subcarriers. Fig. 1 presents system throughput for different number of users at different system SNR values 0 dB, 5 dB, and 10 dB for MIMO-OFDM system where $M = N = 2$, number of subcarriers $L = 64$. It shows that MIMO-OFDM channel provides increased throughput with increase in system SNR value. We will model the MIMO-

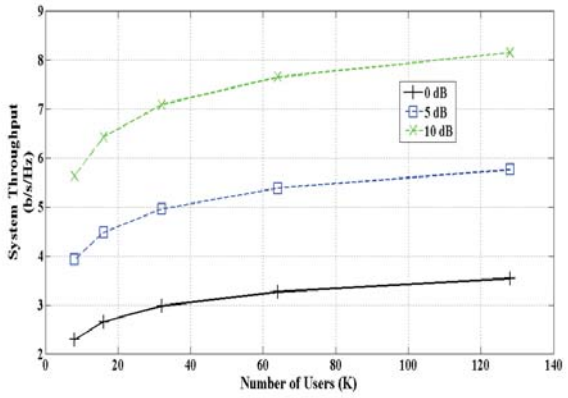

Fig. 1. System throughput of scheme I plotted for different number of users at various system SNR values of 0 dB, 5 dB, and 10 dB for $M = 2$, $N = 2$ and $L = 64$.

OFDM channel using the exponential power delay profile [21] as:

$$\sigma_p^2 = \frac{1 - exp(-1/D_{exp})}{1 - exp(-P/D_{exp})} exp(-p/D_{exp}), 0 \leq p \leq P - 1. \quad (8)$$

Throughout this section, we will use $P = 8$ and $D_{exp} = 2$.

B. Limited Feedback Scheduling: Scheme II

This scheme is similar to the previous one. But in this scheme, a threshold (λ) for SINR is being set and the users feed back their maximum SINR value along with the corresponding transmit antenna indices only if the maximum SINR value is greater than or equal to the threshold value λ as explained in [10] for a specific subcarrier. Again, this process needs to be iterated for all subcarriers. The comparison

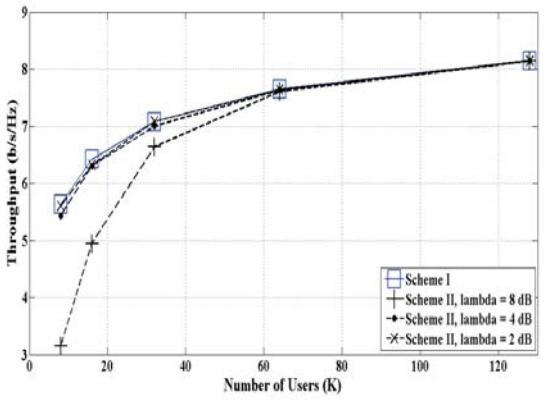

Fig. 2. System throughput of scheme II plotted for different number of users at system SNR of 10 dB for $M = 2$, $N = 2$ and various threshold values as λ= 2 dB, 4 dB, and 8 dB,$L = 64$.

of system throughput of scheme II for different values of threshold λ along with scheme I is presented in Fig. 2. It is evident that the system throughput increases and matches with that of scheme I as the threshold value λ decreases. Also, the feedback overhead increases with decrease of threshold value λ because by decreasing the threshold value λ more number of users will qualify to feedback their maximum SINR values to BS.

C. Limited Feedback Scheduling: Scheme III

In this limited feedback scheduling, each user should send an array of maximum SINR values corresponding to each transmit antenna as discussed in [**?**] for single subcarrier. Here, users do not send the transmit antenna indices like [10]. And the scheduling done at BS is similar to the above explained schemes. All subcarriers need to follow the above steps. The sum rate achieved by MIMO-OFDM by implementing this scheme is presented in Fig. 3. It shows sum rate attained by MIMO-OFDM system with M=N=3, and L=64 for different number of users at various system SNRs like 0dB, 5dB, and 10 dB. Fig. 4 shows the comparison of throughput obtained by scheme I, scheme III for MU MIMO-OFDM with M=N=3, L=64 at various system SNR values as 10 dB and 20 dB. It is shown that scheme III outperforms scheme I in utilizing the spectrum efficiently. One of the drawbacks of scheme I is that when users send only the highest SINR, some better conditioned receive antenna of some other user are not allowed to be served by BS, which could have resulted in better utilization of the spectrum. Also, scheme I may leave some of the transmit antennas idle (when none of the user's maximum SINR value is due to these transmit antennas) without sending useful data packets. This may lead to non exploitation of spatial multiplexing. But the chances of occurrence of such events get decreased with increase in number of active users due to MUD. Hence, scheme III attains better spectrum efficiency than scheme I for less number of users and both the schemes attain similar throughput for higher

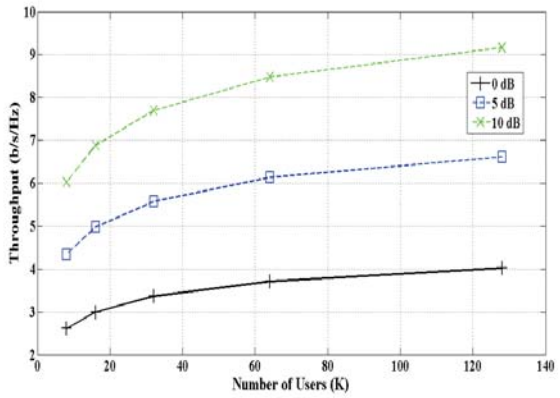

Fig. 3. System throughput of scheme III plotted for different number of users at various system SNR values of 0 dB, 5 dB, and 10 dB for M = 3, N = 3 and L = 64.

number of users.

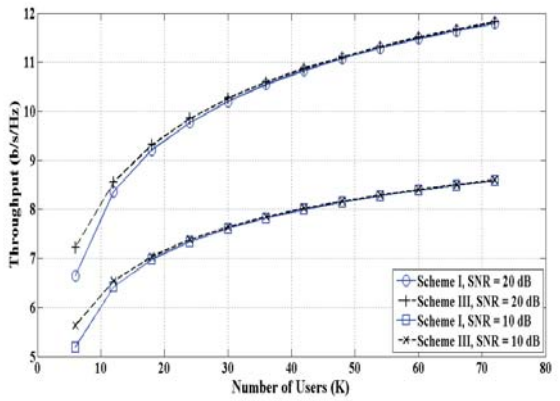

Fig. 4. Comparison of system sum rate of scheme I and scheme III for lesser number of users at various system SNR values of 10 dB, and 20 dB for M = 3, N = 3 and L = 64.

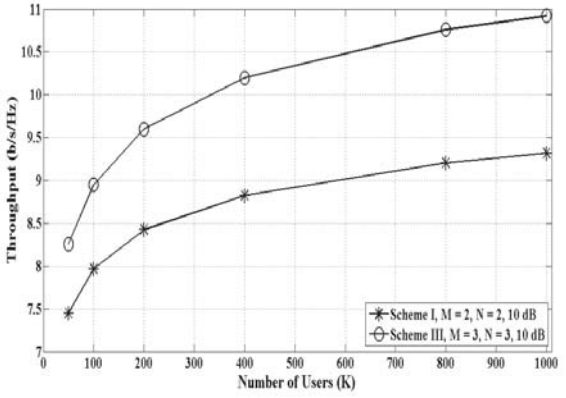

Fig. 5. Comparison of system sum rate of scheme I and scheme III for higher number of users at system SNR of 10 dB for 2×2, and 3×3 MU MIMO-OFDM system respectively with L = 2048.

In Fig. 5, it is interesting to observe that the net throughput of the system obtained by scheme I, and scheme III increase steadily with user size (unlike shown in [19]) because these schemes are able to exploit MUD. Hence, the probability of selecting receive antennas with higher SINR gets increased with number of active users. We have plotted the system throughputs obtained by scheme I and scheme III for MU MIMO-OFDM system with $L = 2048$, SNR = 10 dB for number of transmit and receive antennas are two and three respectively in Fig. 5 . Hence, this result states about the usefulness of these two user scheduling schemes.

D. Per-chunk user scheduling using scheme I and scheme III

When adjacent subcarriers are grouped into a chunk, the feedback overhead incurred by the system decreases by a factor of chunk size [19]. Hence, it is advantageous to use per-chunk user scheduling in the scheduling schemes proposed for MU MIMO system. In this section, we discuss the effect of per-chunk user scheduling in the above discussed schemes. Here, we have presented the modified expressions for system sum rate using SINR and per-chunk user scheduling. Each chunk consists of L_c adjacent subcarriers and integer number of chunks are formed out of the total subcarriers. The total achievable system throughput expressed in (5), now can be expressed by as below:

$$T \leq E\left[\frac{1}{Q}\sum_{q=1}^{Q}\max_{1<k<K} T_{chk,q}^{k}\right], \tag{9}$$

where Q is the total number of chunks in the MIMO-OFDM system and expressed as $Q = L/L_c$.And $T_{chk,q}^{k}$ is the highest instantaneous reliable rate on the chunk q for user k which is expressed in bits/second/hertz and is given by

$$T_{chk,q}^{k} = \frac{1}{L_c}\sum_{l_c=(q-1)L_c}^{qL_c-1} T_{lc}^{k}, 1 \leq q \leq Q, \tag{10}$$

where T_{lc}^{k} is expressed in (7). Comparison of system throughput obtained by user scheduling schemes like scheme I and scheme III with grouping of adjacent subcarriers is shown in Fig. 6. Here, the system throughput obtained by both the algorithms for MU MIMO-OFDM system with M=N=3, L=2048, and L_c=32 is compared. This clearly showcases the usefulness of scheme III over scheme I. This behaviour can also be explained by the explanation given for Fig. 4. But, here it is interesting to observe that the probability of non assignment of better conditioned receive antennas to transmit antennas of BS and leaving some of the transmit antennas idle without transmitting useful data packets occur for more than one subcarrier simultaneously. For this reason, the difference of throughput attained by scheme I and scheme III is more when user scheduling is implemented with grouping of adjacent subcarriers to reduce feedback overhead. It is important to observe that with implementation of per-chunk user scheduling (3×3 MIMO-OFDM system with L = 2048, L_c = 32 at 10 dB system SNR), there is a decrease in system throughput obtained by scheme I and scheme III by 64%, and

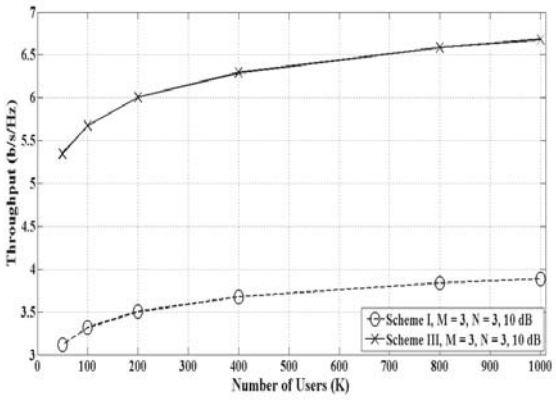

Fig. 6. Comparison of system sum rate of scheme I and scheme III for more number of users at system SNR values of 10 dB for M = 3, N = 3, L = 2048, and L_c=32.

38% respectively (as compared to the throughput obtained by these two schemes without per-chunk user scheduling) while the feedback load is reduced by a factor of 64 (i.e., $\frac{2048}{32}$). Hence, scheme III is always preferable over scheme I and scheme II for MU closed-loop MIMO-OFDM system for both with and without per-chunk user scheduling.

E. Feedback load comparison

We presented a comparison of feedback overhead incurred by these limited feedback scheduling algorithms for MU MIMO-OFDM system in TABLE I. It shows that the feedback load incurred by scheme II depends on the predefined threshold (λ) and the maximum feedback overhead is equal to that of scheme I. The scheme III incurs an insignificant increment in feedback overhead by feeding back an array of maximum SINR values, but it enjoys the advantage of not feeding back transmit antenna indices.

TABLE I
COMPARISON OF FEEDBACK LOAD INCURRED BY SCHEME I, II, AND III FOR MU MIMO-OFDM.

Scheduling Algorithms	**Number of SINR Terms**	**Number of bits representing Transmit Antenna Indices**
Scheme I without per-chunk	$L \times K$	$L \times K \times \lceil log_2(M) \rceil$
Scheme II without per-chunk	$\leq L \times K$	$\leq L \times K \times \lceil log_2(M) \rceil$
Scheme III without per-chunk	$L \times M \times K$	0
Scheme I with per-chunk	$Q \times K$	$Q \times K \times \lceil log_2(M) \rceil$
Scheme III with per-chunk	$Q \times M \times K$	0

IV. CONCLUSION

In this paper, three SINR based MU MIMO-OFDM BC scheduling algorithms are discussed with and without per-chunk user scheduling. The expression for net throughput of MIMO-OFDM system with SINR model is obtained for closed-loop feedback system with and without per-chunk user scheduling. The scheduling scheme III is proved to be better in utilizing the spectrum efficiently compared to scheme I and II for MIMO-OFDM system. Moreover, we showed that the sum-rate achieved by these user scheduling schemes increase with user size unlike the results presented in [19]. In fact, with reduced feedback load by implementing per-chunk user scheduling, scheme III produces much better net throughput than that due to scheme I.

***Abstract*—After the Great East Japan Earthquake, the National Institute of Information and Communications Technology (NICT) researched and developed resilient information and communication technologies, such as a wireless mesh and satellite network. NICT developed three types of earth stations for satellite communication, and dispatched them for use in several disaster countermeasure drills. The usefulness of satellite communication was demonstrated by establishing a temporary communication link.**

Keywords—resilient ICT, satellite commuunication, WINDS, earth station

I. INTRODUCTION

On March 11, 2011, the Great East Japan Earthquake, registering with a magnitude 9.0, struck off Japan's eastern seaboard. There was tremendous amount of damage, including damage to terrestrial networks for telephones and cell phones. This made it extremely difficult for people in the affected areas to communicate with people in other areas. Satellite communication was shown to be one of the better solutions for communication problems during large-scale disasters.

The National Institute of Information and Communications Technology (NICT) has developed resilient information and communications technology facilities. These consist of elements such as wireless mesh networks, satellite communication networks, and optical fiber networks. Three types of earth stations were developed for the disaster countermeasure experiment involving the use of the Ka-band satellite, the Wideband InterNetworking engineering test and Demonstration Satellite (WINDS) [1]. The three earth stations consist of a small mobile vehicle earth station, a large-scale in-vehicle earth station, and a fully-automatic transportable earth station, and they were designed to be easy to set up and operate.

NICT dispatched these earth stations for use in several disaster countermeasure drills. During these drills, WINDS established temporary communication network that worked in coordination with the Unmanned Aeronautical System (UAS) and the wireless mesh network. This paper introduces WINDS, the three types of earth stations described above, and disaster countermeasure drills in which they were used.

II. WINDS[1]

WINDS is an engineering test satellite developed by NICT and Japan Aerospace Exploration Agency (JAXA) to advance high-speed satellite communication network technology. WINDS was launched on February 23, 2008, and is located in a geostationary orbit of 143 degrees east longitude. It uses Ka-band (28 GHz-band for uplink and 18 GHz-band for downlink) for communication between the satellite and earth stations.

The block diagram of the WINDS transponder is shown in Figure 1. WINDS has an onboard switch (ABS) for regenerative relay mode, which demodulates uplink signals, switches, and modulates to downlink. The available data rates for uplink are 1.5, 6, 24, 51, and 155 Mbps, but only 155 Mbps is available for downlink. A time division multiple access (TDMA) system is used and multiple users can use the transponder simultaneously by means of time-slot sharing. A bent-pipe relay can also be used with a 1.1 GHz bandwidth transponder, which bypass ABS. WINDS has two types of antenna: Multi-Beam Antenna (MBA) and Active Phased Array Antenna (APAA). The MBA covers Japan and ten Asian cities, while the APAA has two receiving beams and two transmission beams that can scan around the globe. WINDS can be accessed from anywhere in Asia-Pacific region by using

TABLE I. MAJOR SPECIFICATIONS OF WINDS

Geostationary orbit	143 deg. east longitude
Launch	February 23, 2008
Frequency	Uplink: 27.5 to 28.6 GHz Downlink: 17.7 to 18.8 GHz
Antenna	Multi-beam antenna (MBA) Domestic beam: 12 beams Asian beam: 7 beams Active Phased Array Antenna (APAA): 2 beams
EIRP, G/T	MBA: > 68 dBW, > 18 dB/K APAA: > 55 dBW, > 7 dB/K
Communication mode	Regenerative relay mode Uplink: 1.5, 6, 24, 51, and 155 Mbps Downlink: 155 Mbps Bent-pipe relay mode Up to 3.2 Gbs

the APAA.

The major specifications of WINDS are shown in Table I. The EIRP and G/T of the MBA are approximately 10 dB larger than the APAA.

In the area covered by the MBA, an ultra-small aperture terminal (USAT) with an antenna diameter of 45 cm can transmit at 6 Mbps and receive 155 Mbps using a regenerative relay.

III. Earth Station for Disaster Countermeasure Experiments using WINDS

The occurrence of large disaster highlighted the importance of ICT as a life line. NICT researches and develops resilient ICT networks in cooperation with universities and several companies. A resilient network should include a robust photonic network, dependable wireless and satellite network, and an anti-disaster information distribution platform. Figure 2 shows the dependable wireless mesh and satellite networks[2], [3].

NICT developed three types of earth stations for the resilient network experiment using WINDS. The three earth stations consist of a small mobile vehicle earth station, a large-scale in-vehicle earth station, and a fully-automatic transportable earth station, and they were designed to be easy to set up and operate.

A. Small mobile vehicle earth station[4], [5], [6]

A small mobile vehicle earth station was developed to communicate with the satellite while in motion so that the team dispatched to the affected area can obtain the most up-to-date

TABLE II. MAJOR SPECIFICATIONS OF SMALL MOBILE VEHICLE EARTH STATION

Tx frequency	27.5 to 28.6 GHz
Rx frequency	17.7 to 18.8 GHz
Polarization	Liner (H/V)
Antenna	0.65 m Cassegrain
HPA	20 W TWTA
Drive range	El: 20 to 90 degrees Az: Unlimited
Tracking accuracy	< +/-0.2deg.
Data rate	WINDS regenerative transponder Tx:1.5, 6, 24 Mbps Rx: 155 Mbps
Electric generator	2.8 kVA
User interface	Ethernet (1000base-T)

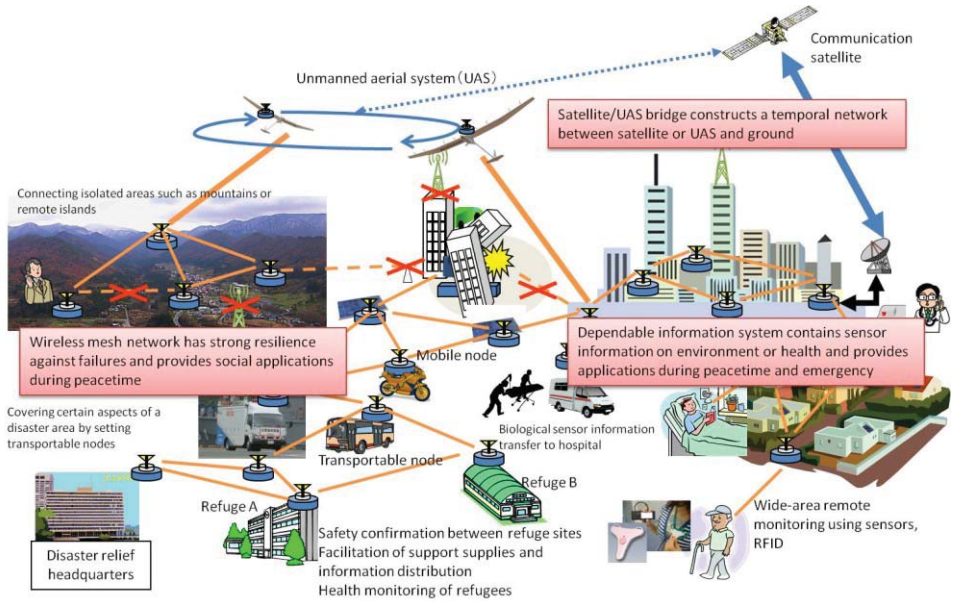

Figure 2. Dependable wireless mesh and satellite networks

Figure 3. Small mobile vehicle earth station.

information about the disaster, and modify its action plan in coordination with the dispatching agency.

This earth station is installed in a test van, such as the one shown in Figure 3, and the major specifications are listed in Table II. The antenna size is 0.65 m, and the output power of the high power amplifier is 20 W. The tracking accuracy is within +/- 0.2 deg. This earth station has an interlock function that disables transmissions when the signal to be received is small. A HDTV camera is installed on the roof, and the image can be transmitted to a satellite link.

B. Large-scale in-vehicle earth station[4], [5]

A large-scale in-vehicle earth station was developed so that it could function as a communication hub that combines the functions of satellite communication and wireless terrestrial network when it is dispatched to an affected area. This earth station is installed in a truck, such as the one shown in Figure 4, and the major specifications are listed in Table III. The antenna diameter is 2.4 m, and the output power of the high power amplifier is 175 W. The antenna is put away during transport and deployed upon arrival at the location from which it will communicate with the satellite. The earth station has an electric 8.5 kVA generator that can power the earth station and terrestrial network equipment.

C. Fully-automatic transportable earth station[4], [5]

When a disaster occurs, it may not be possible for experts

TABLE III. MAJOR SPECIFICATIONS OF LARGE-SCALE IN- VEHICLE EARTH STATION

Tx frequency	27.5 to 28.6 GHz
Rx frequency	17.7 to 18.8 GHz

to keep all the earth stations for satellite communications running. NICT developed a fully-automatic transportable earth station that can be installed and easily operated by individuals who are not experts.

Figure 5 shows a picture of the fully-automatic transportable earth station, the major specifications of which are listed in Table IV. The antenna diameter is 1.0 m and the power of the high power amplifier is 75 W. The earth station has a GPS compass that detects the position of the earth station and the direction of the antenna. The earth station can point the antenna in the direction of the satellite.

When using this earth station, we can transmit up to 51 Mbps and receive 155 Mbps using the WINDS regenerative transponder.

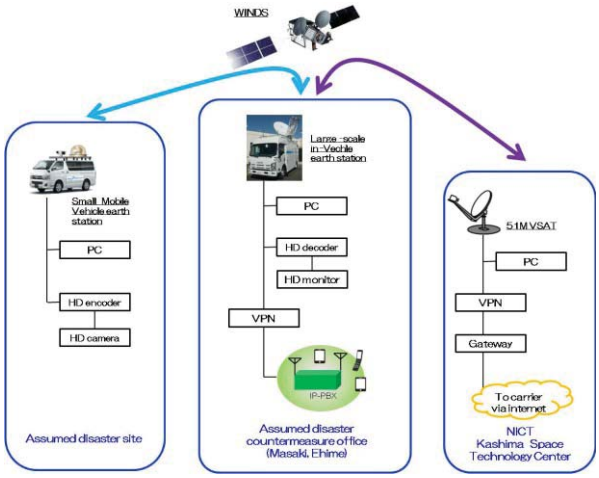

Figure 6. Network configuration of Ehime disaster prevention drill.

IV. DISASTER COUNTERMEASURE EXPERIMENTS USING WINDS

NICT participated in the disaster prevention drills conducted at various locations across Japan, providing satellite communication linkage through the use of WINDS. The following section takes a look at some of these drills.

A. Ehime prefecture disaster prevention drill

NICT dispatched a small mobile vehicle earth station and a large-scale in-vehicle earth station to participate in the Ehime disaster prevention drill. Ehime is located in the north of Shikoku, and is expected to suffer heavy damage when the next Nankai trough earthquake occurs. For this reason, the prefecture has placed emphasis on disaster prevention drills. The network configuration is shown in Figure 6. As the small mobile vehicle earth station tracked a transportation truck, it transmitted the video to the large-scale in-vehicle earth station that had been set up in the disaster countermeasure office. The large-scale earth station was connected to the NICT Kashima Space Technology Center (KSTC) via WINDS, with KSTC serving as the gateway to the Internet. In addition, the IP-PBX was installed on a large-scale in-vehicle earth station, and a demonstration of the temporary base station was given in an affected area where cell-phones could not be used. IP-PBX is a device that performs the circuit switching of the IP telephone terminal in an IP network. The data from IP-PBX was transmitted to the cell-phones carrier, enabling us to communicate with the public network.

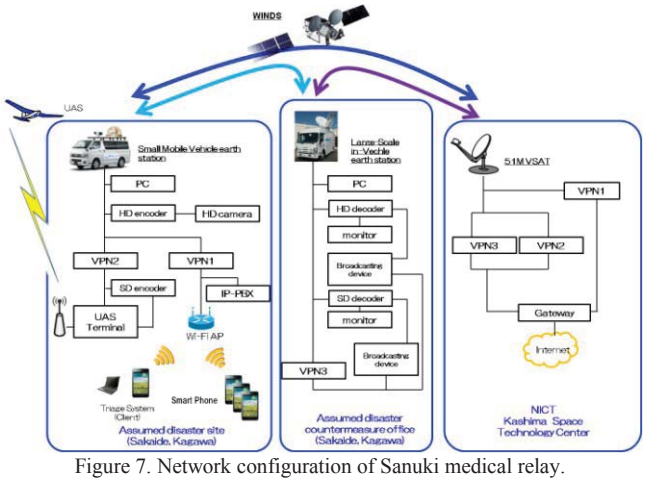

Figure 7. Network configuration of Sanuki medical relay.

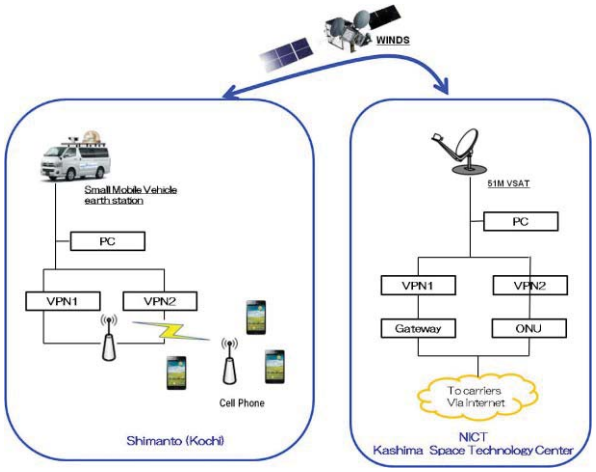

Figure 8. Network configuration of Femto-cell connection experiment.

B. Sanuki medical relay

Triage training using a satellite link and a digital triage tag system with digital pen was performed under the assumption that the terrestrial communication line would suffer damage during a large-scale disaster. NICT dispatched a small mobile vehicle earth station and a large-scale in-vehicle earth station to establish the satellite link using WINDS. The small mobile vehicle earth station was set up at the place where training was conducted, and the large-scale in-vehicle earth station was set up at the assumed disaster countermeasure office. The network configuration is as shown in Figure 7. Both earth stations were connected with KSTC, and could use Internet. The state of the training place was shot with a video camera set up on the small mobile vehicle earth station, and then transmitted to the assumed disaster countermeasure office and distributed to the Internet. An unmanned aeronautical system (UAS) served as the communication repeater and the camera from the sky. The data was transmitted to the small mobile vehicle earth station and distributed to the assumed disaster countermeasure office.

C. Femto-cell connection experiment using satellite links[7]

A femto-cell connection experiment was carried out under the assumption that temporary cell phone network would be established in an affected area where cell-phones could not be used.

The wireless mesh network was connected with the small mobile earth station and the femto-cell station. The small mobile earth station was connected with the cell-phone carriers through the KSTC via WINDS and Internet. The network configuration is as shown in Figure 8.

The delay in the satellite link was not a major concern, and good communication was established.

D. Japan Medical Association disaster prevention drill

NICT participated in Japan Medical Association (JMA) disaster prevention drill with JAXA and established a communication link using WINDS. The drill was conducted

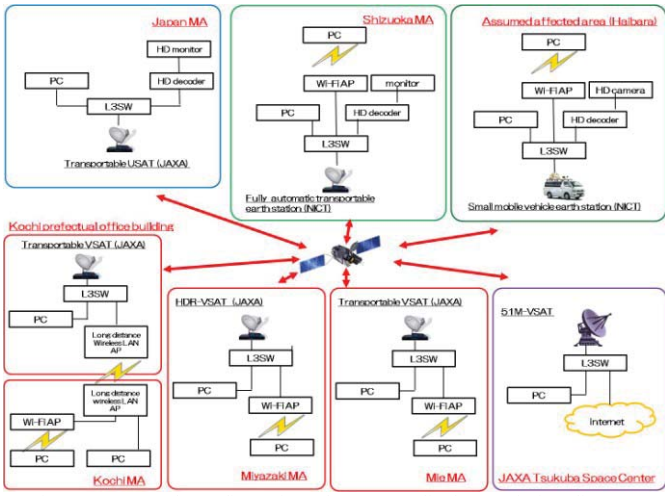

Figure 9. Network configuration of Japan Medical Association disaster prevention drill.

under the assumption that the next Nankai trough earthquake had occurred. NICT and JAXA set up WINDS terminals at five medical associations (MA), including associations in Shizuoka, Mie, Kochi, and Miyazaki Prefectures, as well as the JMA. NICT dispatched a fully-automatic transportable station to the Shizuoka MA and a small mobile earth station to Haibara in Shizuoka prefecture, based on the assumption that these two areas would be affected by the earthquake. The High-Data-Rate Very Small Aperture Terminal (HDR-VSAT) at the JAXA Tsukuba Space Center was connected to the Internet. The applications of the web meeting system used all the terminals, and HD video was transmitted from the small mobile vehicle earth station in Haibara to the Shizuoka MA and the JMA.

As a result, the effectiveness of sharing information among multiple points was demonstrated.

V. Conclusion

NICT developed resilient ICT facilities consisting of three types of earth stations for satellite communication network: a small mobile vehicle earth station, a large-scale in-vehicle earth station, and a fully-automatic transportable earth station.

These earth stations were participated in several disaster prevention drills to establish temporary communication link using WINDS. The possibility of many different applications was demonstrated by the satellite link connecting with the terrestrial network, such as the wireless mesh network. Video transmission from the small mobile vehicle earth station while moving was very useful for situation grasp and it became possible to deliver it to many points because of connecting to the internet.

An effective communication system technology will be developed when disasters occur, including the establishment of a connection with a satellite link and a wireless network between vehicles on the move.

Acknowledgment

The authors would like to thank the organizations involved with the disaster prevention drills, such as Ministry of Internal Affairs and communications, JAXA and JMA.

***Abstract*—Applications of wireless communications to device-to-device without centralized coordination attract more and more attentions. We designed and developed a test bed of infrastructure independent wireless network that connects end devices directly without central control. Various types of end devices are implemented and used for different scenarios. There is neither conventional base station nor access point, so as to avoid the single-point-of-failure problem when accident or emergency happens. In this paper, we introduce the developed test bed of distributed peer aware communication networks. Since the MAC frame design is one of central importance for the whole system. It directly affects the delivery latency as well as system capacity. We mainly study and evaluate the system performance with different MAC frame designs using our experimental test bed.**

***Index Terms*—Device-to-Device (D2D), Peer Aware Communications (PAC), distributed control, MAC frame, solt allocation, field experiment.**

I. Introduction

To meet the ever-increasing demands on wide coverage and high capacity in wireless mobile communications, how to improve the spectrum utilization becomes more and more important. Heterogeneous network is one of the technologies that introduce multi-layer network structure in order to deal with off-load traffic [1]–[3]. On the other hand, applications of wireless communications to device-to-device (D2D) and machine-to-machine (M2M) attract more and more attentions. Moreover, in case that the existing infrastructures fail to work due to disaster like earthquake or other reasons, it is desirable that wireless devices distributedly form a network for information delivery without needing infrastructures [4]. D2D is also expected to play active roles in the Internet of Things [5] as well as in mobile social networks [6].

With the above-mentioned demand, the IEEE 802 Standardization Committee set up a task group of TG15.8 (IEEE 802.15.8) to develop a new standard for infrastructureless Peer Aware Communications (PAC). There is neither conventional base station (BS) nor access point (AP) in PAC network. Therefore, single point of failure (SPOF) due to inability of BS and AP as in conventional centralized control network will not happen. PAC can be used for information sharing and emergency communication by distributed in buses and neighbor community.

The IEEE 802.15.8 defines physical and media access control (MAC) mechanism for wireless personal area networks (WPAN) PAC with fully distributed coordination. PAC is a sort of mobile ad-hoc network (MANET) techniques and its features include (a) discovery for peer information without association, (b) discovery signaling rate, typically 100kbps, (c) the number of devices in the discovery, scalable data transmission rates, typically 10 Mbps, (d) group communication with simultaneous membership in multiple groups, typically up to 10, (e) relative positioning, (f) multi-hop relay, (g) security, (h) and operational in selected globally available unlicensed/licensed bands below 11 GHz capable of supporting these requirements [7]. The applications for PAC with multicast can support various new applications, such as social network service (SNS), local advertisement, emergency service, vehicle location service, game, audio/video streaming applications, proximity device control, P2P services, etc.

We has studied PHY and MAC mechanism and proposed MAC proposals for PAC standardization working group [8]–[11]. We focused on multiple group/network forming problem among a number of devices of proximities that are deployed in a local area, where a group operation algorithm was proposed based on distributed control [12]. In this paper, we provide a brief overview of our experimental test-bed which is deployed in two real fields: one is Odaiba area of Tokyo as a typical urban model and another is Seika Town of Kyoto as a typical rural model for field evaluation. This test bed is designed and developed as a precursor system based on the concept of PAC. Since the MAC frame design (time slot allocation) is one of central importance for the whole system. It directly affects the delivery latency as well as system capacity. We mainly study and evaluate the system performance with different MAC frame designs using the experimental test bed in this work.

The remainder of this paper is organized as follows. Sect. II describes the structure of PAC system. Sect. III describes an overview of PAC experimental test-bed and MAC frame designs. Sect. IV describes the field evaluation scenarios and experiment results. Sect. V includes our concluding remarks.

II. Peer Aware Communications (PAC) System

In the PAC system, there is no central control BS. If PAC devices come into the communication range, information can be exchanged with each other directly. The collection and

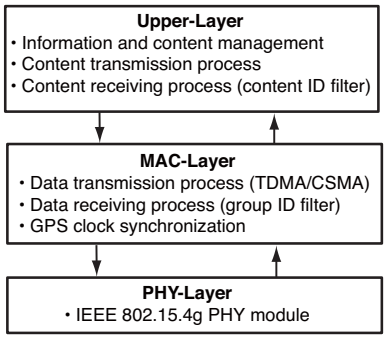

Fig. 1. Peer aware communications (PAC) system structure.

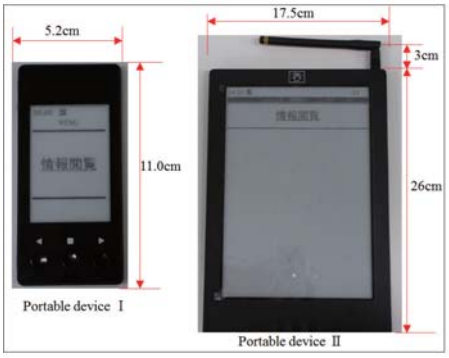

Fig. 2. Two types of portable PAC devices: Portable-I and Portable-II.

Fig. 3. Signage type PAC devices: (a) stationary version (Signage-P) and (b) vehicle-mounted version in a bus (Signage-B).

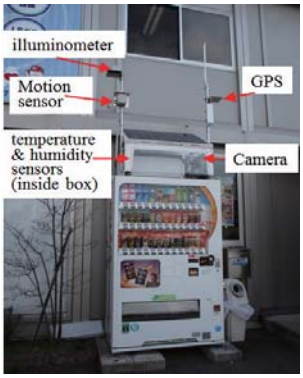

Fig. 4. Sensor type PAC device (Sensor-D) located on a vending machine.

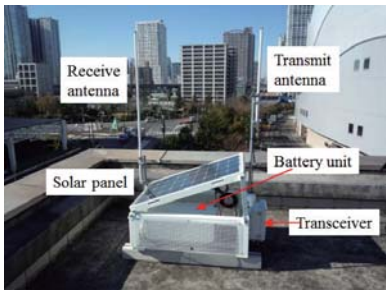

Fig. 5. High power PAC device (High-D) located on the rooftop of building.

diffusion of information are performed by either people or vehicles carrying PAC devices in fully distributed fashion. Based on the above features, we originally developed a experimental PAC test-bed. The structure of PAC system is shown in Fig. 1, where the MAC-layer protocol is designed by our original way. The IEEE 802.15.4g PHY module is applied in this PAC device.

We designed four types of PAC devices in the test bed include portable devices (type I and type II) that can be carried by person as shown in Fig. 2, signage devices that can be mounted in bus or laid in public building as shown in Fig. 3, sensor devices that are distributed in local area to gather weather and other data as shown in Fig. 4, high power device that can be mounted on the roof of a building and has a much larger coverage than the other devices as shown in Fig. 5.

All above devices have limited communication range. If a device needs to communicate with other devices exceeding the range, relay and multi-hop are necessary. It should be noted that we designed a message/data holding function for all devices. The signage device mounted in the bus (Signage-B) can directly communicate with other devices in surroundings, such as the signage devices in a hotel, in a local administration office, and/or in a shopping mall (Signage-P), sensor device (Sensor-D), portable device I (Portable-I) carried by person, as well as portable device II (Portable-II) used in houses and offices.

As bus moves, the signage-B communicates with new devices it connects to. On one hand, it diffuses information/data that it holds. On the other hand, signage-B collects data or receive message from those connected devices. In such a manner, information are collected and/or diffused gradually within the local area as buses move. This is also available with portable devices. In some case, such as the emergency alarm and bus location information, it need to be delivered in quasi-real time. To address this requirement, high power device (High-D) is used for broadcasting high-priority information to all PAC devices, of course it is operated in distributed fashion. By enabling direct link between High-Ds, the delivery latency of data can be minimized.

The devices sketched in the foregoing section are installed using a 920 MHz module. This module is implemented based

on ARIB STD-T108 [13]. It occupies 400kHz bandwidth as a single channel and achieves 115.2kbps data rate by employing binary GFSK modulation. CRC-16 is adopted for error detection. The maximum permitted equivalent-isotropically-radiated-power (e.i.r.p.) is 250mW for high-D and 20mW for other devices. It should be noted that 250mW is of the similar order of e.i.r.p. of a mobile phone. The communication range with line-of-sight (LOS) is about 900m between a pair of 20mW devices and about 3km between a 20mW devices and a 250mW device. Moreover, although there are a dozen of channels available, we use a fixed channel with a center frequency at 922.5 MHz in the test bed.

Main components of each type of device are summarized in TABLE 1. Signage devices and portable devices are installed with display and user I/O interface while Sensor-D and High-D are not. This is because that Sensor-D and High-D do not interact with users directly.

TABLE I
VARIOUS DEVICES AND THEIR MAIN COMPONENTS

Device Type	Main Components
Protable-I (2.7-inch EPD)	920MHz module, plane-type antenna, 3D motion sensor, GPS kit, user I/O interface, lithium ion battery, elctrical paper display (EPD)
Protable-II (9.7-inch EPD)	
Signage-P	920MHz module, dipole antenna, 21.5-inch display, GPS kit, user I/O interface, CF and SD.
Signage-B	
High-D	920MHz module, dipole antennas, solar power system
Sensor-D	920MHz module, dipole antennas, temperature and humidity sensor, video camera, motion sensor, illuminometer, solar power system

III. TEST-BED DEPLOYMENT AND MAC FRAME DESIGN

A. Test-Bed Deployment

We chose two different fields to experimentally deploy the developed test bed. The first field is the Seika Town in Kyoto prefecture, which is a typical rural area with scarcely scattered high buildings and small hills. The test bed is deployed alone the route of a commuter bus which is known as *Seika KURURIN*. The bus route and devices deployed in the area are depicted on a local map shown in Fig. 6. Three buses serve for this route. The second test field is the Odaiba Area in Tokyo, which is a famous tourist resort and a typical urban model with dense of high buildings. The test bed is mainly deployed alone the route of a commuter bus which is known as *Odaiba Rainbow Bus*. Route of the bus and devices deployed are depicted on a local map shown in Fig. 7.

TABLE II summarizes all devices deployed in the two areas. It can be seen that the number of Odaiba Rainbow Bus is seven to provide frequent transportation, while the bus of Seika KURURIN is three. On the other hand, sensor devices are only deployed in Seika Town, where it is convenient to find places to mount the devices. Other devices are deployed equally. A remote PC server is used in our laboratory for monitoring and analysis purposes, which is connected to particular signage devices through internet.

TABLE II

Area	Signage -B	Signage -P	Sensor -D	High -D	Portable -I	Portable -II
Seika	3	5	8	5	10	10
Odaiba	7	5	0	5	10	10

B. MAC Frame Design: TDMA/CSMA Channel Access

The MAC frame design is one of central importance for the whole system. It directly affects the delivery latency as well as system capacity. In this work, we design three different MAC frame patterns as shown in Fig. 8 and evaluate the system performance using our test bed at Seika-Town of Kyoto prefecture. Since our PAC system may include high-priority information such as emergency information, that must be delivered to all devices using the High-D within a super

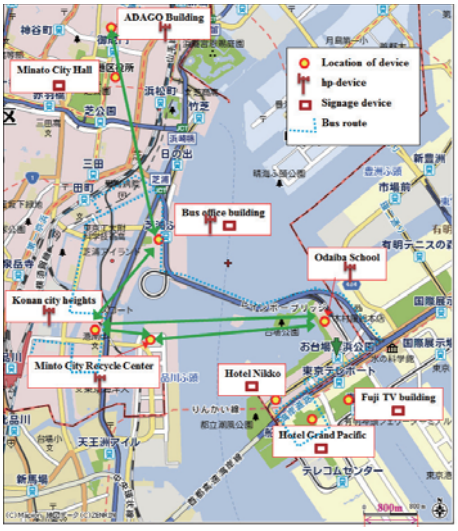

Fig. 7. Test-bed deployment at Odaiba area Tokyo.

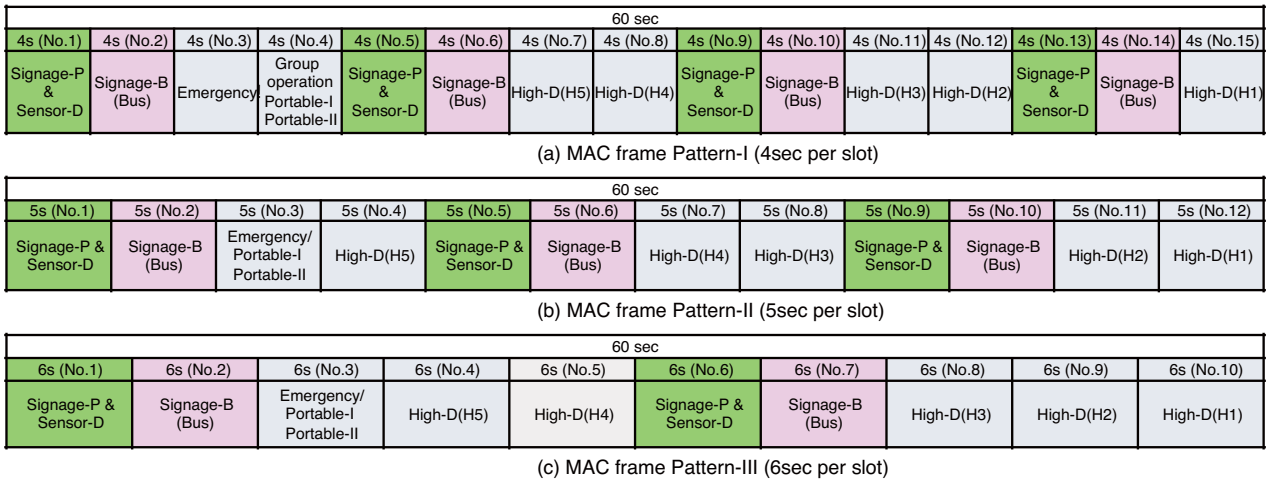

Fig. 8. Time slot allocation patterns in a super MAC frame.

MAC frame. The duration of a super MAC frame is set as 60s for all frame patterns. In each slot (4s, 5s and 6s), CSMA channel access is operated by the PAC devices.

MAC frame *Pattern-I* shown in Fig. 8 (a): there are total 15 slots in a super MAC frame and each has a length of 4s. Because that Signage-B, Signage-P and Sensor-D play more active roles, they are assigned with periodic slots in the frame, i.e., once every four slots for routine access (except the last three slots). Five slots are assigned to each High-D exclusively, that are distributed in slot no.7, no.8, no.11, no.12 and no.15. The purpose is to avoid interference between High-Ds since they have much large coverage. Slot no.3 is assigned for sending urgent message. Slot no.4 is assigned for group operation of the Portable-I and II users.

MAC frame *Pattern-II* shown in Fig. 8 (b): there are total 12 slots in a super MAC frame and each has a length of 5s. Three slots are assigned to Signage-P and Sensor-D in slot no.1, no.5 and no.9. Another three slots are assigned to Signage-B in slot no.2, no.6 and no.10. Five 5s slots are assigned to each High-D exclusively, that are distributed in slot no.4, no.7, no.8, no.11 and no.12. Slot no.3 is assigned for group operation and sending urgent message.

MAC frame *Pattern-III* shown in Fig. 8 (c): there are total 10 slots in a super MAC frame and each has a length of 6s. Two 6s slots are assigned to Signage-B. Five 6s slots are assigned to each High-D exclusively, that are distributed in slot no.4, no.5, no.8, no.9 and no.10. Slot no.3 is assigned for group operation and sending urgent message.

IV. PAC Test-bed Performance Evaluation

Since the MAC frame design is one of central importance for the whole system, we evaluate the system performance using three different MAC frame patterns at our test-bed of Seika-Town Kyoto prefecture as shown in Fig. 6. There are two scenarios considered for the PAC system performance evaluation: (i) data collection and delivery using sensor device (Sensor-D) and high power device (High-D), and (ii) data delivery using signage devices (Signage-P and Signage-B).

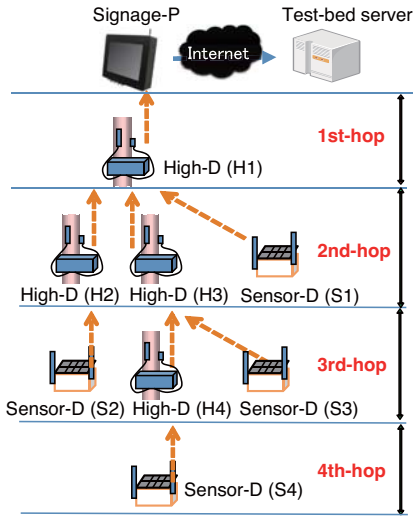

Fig. 9. Evaluation scenario of sensor device (Sensor-D) data multi-hop delivering via high power device (High-D).

A. Evaluation Scenario I: Sensor Data Multi-hop Delivery

The image of the sensor data multi-hop delivery scenario is shown in Fig. 9, where each Sensor-D delivers its data to a gate front Signage-P via High-D. For example, the Sensor-D (S4) needs four hops to deliver its data to the gate front Signage-P: Sensor-D (S4) ⇒ High-D (H4) ⇒ High-D (H3) ⇒ High-D (H1) ⇒ Signage-P. The Sensor-D (S1) needs two hops to deliver its data to the gate front Signage-P: Sensor-D (S1) ⇒ High-D (H1) ⇒ Signage-P. We measure the data necessary delivering time between Sensor-D and Signage-P using three different MAC frame patterns.

The experimental results of each Sensor-D's data delivering time are shown in Fig. 10. We observe that using MAC frame

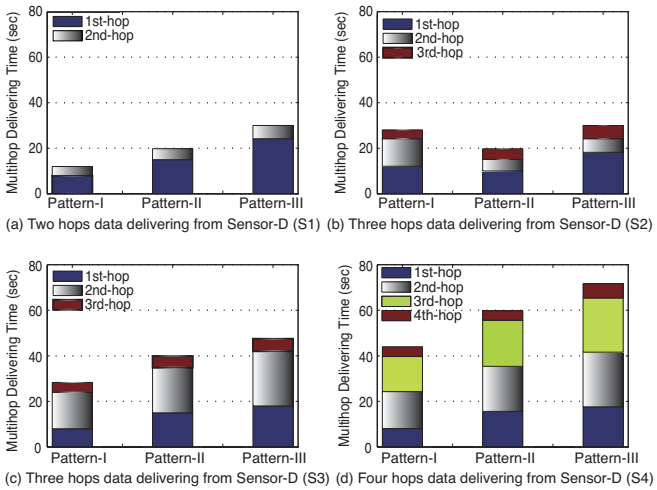

Fig. 10. Experimental results of sensor device (Sensor-D) data multi-hop delivering via high power device (High-D).

Pattern-I can achieve almost the shortest delivering time, and using Pattern-III achieves the longest delivering time. The reason is that in a super MAC frame of Pattern-I there are more chances (slots) allocated to Sensor-D to sending its data than Pattern-II and Pattern-III. Pattern-I has 4 slots allocated to Sensor-D, while Pattern-III has only 2 slots allocated to Sensor-D as shown in Fig. 8.

B. Evaluation Scenario II: Signage-P Data Relaying via Signage-B

The scenario image of the stationary signage device (Signage-P) data relaying via vehicle-mounted signage device (Signage-B) is shown in Fig. 11, where the signage data is delivered by the Signage-B from a gate front Signage-P to other Signage-Ps. In this scenario, we increase the data size by 0.2kbyte as a increment unit and measure the maximum deliverable data size per slot using different MAC frame patterns.

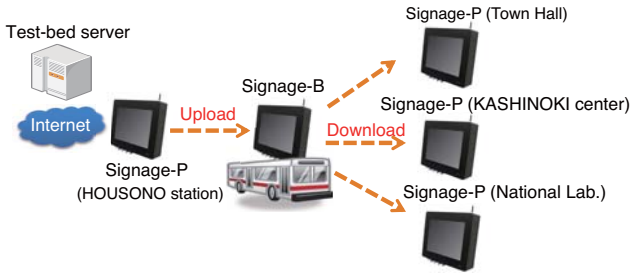

Fig. 11. Evaluation scenario of stationary signage device (Signage-P) data relaying via vehicle-mounted signage device (Signage-B).

The experimental result of scenario II is shown in TABLE III. Pattern-III can upload and download the largest data size in the designed frame patterns. Since the reliability is an important issue for the data transmission, we also find the maximum data size to secure the 90% success rate for each of the three frame patterns.

TABLE III
DELIVERABLE DATA SIZE PER SLOT FOR DIFFERENT FRAME PATTERNS.

	Pattern-I	Pattern-II	Pattern-III
Largest data size	19.8kbyte	25kbyte	30.4kbyte
Maximum data size to secure 90% success rate	19kbyte	24kbyte	29.2kbyte

V. CONCLUSIONS

We developed a test bed of infrastructure independent wireless network that connects end devices directly without central control. The test bed demonstrates a solution for PAC network, which is currently under standardization process as IEEE802.15.8. We deployed the test bed in a typical rural field as well as in an urban field respectively. Data collection and diffusion among local community are conducted and examined through the test bed. Since the MAC frame design is one of central importance for the whole system. We designed three different MAC frame patterns and evaluated the system performance using our test-bed at Seika-Town of Kyoto prefecture. Our field experiment results reveal that frame pattern directly affects the delivery latency as well as system capacity.

***Abstract*— In this paper we study the time switching based energy harvesting (EH) and information transmission protocol for an underlay cognitive relay network where the transmit power of secondary transmitter as well as secondary relay is limited so as to maintain a constraint on QoS of primary user in terms of primary outage. We study the performance of such underlay cognitive relay network with decode and forward (DF) relaying scheme in terms of throughput. A power control law for energy harvesting secondary relay is designed so as to maintain the interference constraint at the PU receiver. The impact of allowable interference threshold (I_{th}), PU outage constraint (δ) and harvesting energy time (α) on throughput of secondary user (SU) and the average transmit power of relay is also studied. Further the impact of tolerable interference threshold, PU outage constraint on the throughput of SU is indicated.**

Keywords—Energy harvestingt;decode and forward; throughput;outage constraint.

I. INTRODUCTION

Cognitive radio has been proposed as an efficient way to strike a balance between spectrum scarcity and spectrum underutilization problem by allocating temporarily the unused spectrum to the unlicensed secondary user (SU). Underlay spectrum sharing is one of the potential techniques where both the primary user (PU) as well as secondary user concurrently utilizes the same spectral band provided the interference produced at the PU receiver due to transmission of SU is below the interference threshold of the PU [1-3]. As the transmit power of SU in underlay technique is controlled in order to protect the PU receiver, the performance of SU is limited in terms of coverage area and outage performance. Cooperative relays are the potential techniques used to enhance the system performance in terms of coverage area and as well as SINR by using spatial diversity. A combination of cooperative relay and cognitive radio is used in order to improve the secondary performance [4-5]. In the recent year there has been significant attention on the energy harvesting relays in connection with cooperative communication. The concept of harvesting energy from ambient RF signal and simultaneous information delivery by the relay has been studied in [6-8]. In [8] the performance of SU has been evaluated in terms of outage probability with energy harvesting and information transfer protocol in an underlay scenario. A general cooperative network based on decode and forward relaying has been studied in [9] where the relay is assumed to harvest energy from the RF transmission from the source. Throughput and ergodic capacity of such network is studied for two energy harvesting schemes based on time switching and power splitting respectively. It is interesting to study the network performance of cooperative network based on energy harvesting relay for an underlay cognitive network scenario. Analyzing the performance of cognitive relay network with energy harvesting under spectrum sharing approach is an important research issue. The performance of different relaying scheme, amplify and forward (AF), decode and forward (DF) in terms of outage probability under energy constraint relays are studied in [10-11]. The performance of SU with energy harvesting DF relaying in an underlay scenario has been studied in [11]. In this present paper we extend the concept of time switching based energy harvesting to an underlay cognitive relay network where the secondary relay (SR) harvests energy from the RF signal transmitted by SU and the transmit power of secondary transmitter as well as SR is limited so as to maintain a constraint on QoS of PU in terms of primary outage. The secondary relay selects its transmit power based on harvested energy and outage constraint of PU. The transmit power of the relay is chosen in any one of the two possible modes, (i) the maximum possible power level corresponding to harvested energy (ii) the maximum power level corresponding to outage constraint of PU. Throughput of underlay cognitive relay network is evaluated under such scenario. The impact of several network parameters such as QoS of PU in terms of maximum tolerable interference, outage constraint, on secondary throughput is investigated. The contributions of our paper are:

- An analytical framework is developed to evaluate performance of underlay cognitive relay network with energy harvesting relay.
- Impact of maximum tolerable interference threshold (I_{th}) at primary receiver (PU-Rx), primary outage constraint (δ) and fraction of time frame (α) allocated for energy harvesting on overall throughput of secondary network is investigated.
- Development of a simulation test bed in MATLAB to validate analytical formulation.
- Formulating a power control law for energy harvesting of secondary relay. We derive the average transmit

power of relay highlighting the impact of I_{th}, δ, and α on average transmit power.

The remainder of the paper is organized as follow: Section II describes the system model considered for this paper. In Section III, we derive the expression for throughput of the network. Section IV shows the numerical results on throughput and average power of relay . Finally, Section V concludes the paper.

II. System Model

The system model considered in our work consists of a SU transmitter (SU-Tx), a secondary relay (SR), a secondary destination (SU-Rx) and a PU receiver (PU-Rx) as shown in Fig. 1. We assume that there is no direct link between SU-Tx and SU-Rx and hence SU transmission is assisted by SR working in DF mode. We assume that the DF relay harvests energy from the source signal. The relay uses the harvested energy as a source of transmit power while maintaining the interference produced at PU receiver below a interference threshold. The relay is assumed to harvest energy for a fraction of time (αT) of the total time frame T and the half of remaining time i.e. (1-α)T/2 is used for source to relay information transmission and the other half, (1-α)T/2 for relay to destination information transmission. The relay is assumed to perform the joint task of energy harvesting and information processing [6]. In underlay the transmit power of SU and relay are controlled so as to maintain an outage constraint imposed by PU based on a given interference threshold. The harvested energy is used as a source of transmit power, ($P_r^{harvest}$) in order to forward the information from relay to destination. The transmit power of the relay is derived from harvested energy only. However there are two cases for the level of transmitted power from relay (i) in case the maximum possible transmit power based on harvested energy ($P_r^{harvest}$) is less than the maximum allowed transmit power $\left(P_r^{\max}\right)$ due to outage constraint of PU, the relay transmits with power $P_r^{harvest}$, we consider the relay to work in mode 1 and call it as *transmission in harvest power mode* otherwise (ii) if $P_r^{harvest}$ exceeds $P_r^{\max}$, the transmission power of the relay is limited to $P_r^{\max}$, and we call this as mode 2 which is *underlay constrained power mode*.

Let h_{sp}, h_{rp}, h_{sr}, and h_{rd} denote the instantaneous fading coefficients of the links from SU-Tx to PU-Rx, from SR to PU-Rx, SU-Tx to SR, and SR to SU destination respectively. All the links are assumed to be independent and identically distributed Rayleigh fading channel with zero mean and unity variance. Therefore the channel power gain, $g_{xy} = |h_{xy}|^2$ is exponentially distributed, where x,y= {s,r}or {p,d}.

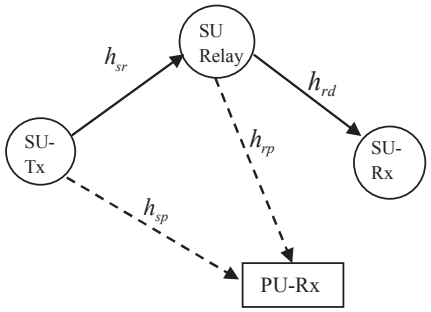

Fig. 1. (a) System model for cognitive relay network.

III. Throughput Under Time Switching Based Relaying

In this section the throughput of the network is analyzed considering a time switching based relaying (TSR) scheme of energy harvesting as in [9]. The transmission block structure in the time switching based relaying scheme is shown in Fig. 2. In the first time frame the SU transmits signal with a power evaluated under a given outage constraint of PU. The relay uses a fraction of block time α $(0 < \alpha < 1)$ for harvesting energy from the source signal. The half of the remaining time frame $(1-\alpha)T/2$ is used for source to relay information transmission and the remaining time frame, $(1-\alpha)T/2$ is used for relay to destination information transmission. However the transmit power of relay is controlled in order to protect the PU from harmful interference due to relay transmission. The relay transmits either in mode 1 with transmit power $P_r^{harvest}$ or in mode 2 with transmit power $P_r^{\max}$ depending on the interference constraint of PU as described before.

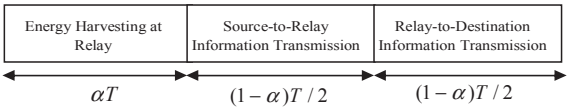

Fig. 2. Transmission block structure for energy harvesting and information transmission.

It may be noted that the relay and the SU do not transmit simultaneously. The outage probabilities of PU constrained by a maximum limit (δ) depending on QoS of PU, due to SU and relay transmissions are given as

$$P_{out-su}^{PU} = \Pr\{P_s^{\max} g_{sp} > I_{th}\} \le \delta \quad (1)$$

$$P_{out-Rel}^{PU} = \Pr\{P_r^{\max} g_{rp} > I_{th}\} \le \delta \quad (2)$$

In writing eq. (1) and eq. (2) we assume the perfect CSI between the SU-Tx and PU-Rx i.e. (g_{sp}) as well as between the SR and PU-Rx (i.e. g_{rp}) is available. The case of imperfect CSI is under investigation by us.

The maximum transmit powers of SU and relay due to underlay constraint are evaluated by equating the above eq. (1) and (2) to δ as:

$$P_s^{\max} = -\frac{I_{th}}{\log(\delta)} \quad (3)$$

$$P_r^{\max} = -\frac{I_{th}}{\log(\delta)} \tag{4}$$

The relay harvests the energy during the time, αT and uses it as a source of transmit power to forward the information during time (1-α)T/2 maintaining an outage constraint (δ) at PU-Rx. The harvested energy at the relay is given as [13]

$$E_h = \frac{\eta P_s^{\max} g_{sr}}{d_1^{\,m}} \alpha T \tag{5}$$

The maximum transmit power of relay available from the harvested energy is given as

$$\begin{aligned} P_r^{harvest} &= \frac{E_h}{(1-\alpha)T/2} \\ &= \frac{\eta P_s^{\max} g_{sr} \alpha}{d_1^{\,m}(1-\alpha)} \end{aligned} \tag{6}$$

where $0<\eta<1$ is the energy conversion efficiency and depends on the energy harvesting circuitry and 'd_1' and 'm' are distance between the source and relay; and m is the path loss exponent. Therefore the transmit power of the relay is given as

$$P_r = P_r^{harvest} \quad if\ P_r^{harvest} \le P_r^{\max} \tag{7.1}$$

$$= P_r^{\max} \quad if\ P_r^{harvest} > P_r^{\max} \tag{7.2}$$

Thus in (7.1) the relay transmits in harvest power mode, while (7.2) indicates the transmit power in underlay constrained mode. Let us assume that relay transmits in harvest power mode with probability 'p_1' while it transmits in underlay constrained mode with probability 'p_2' given as

$$\begin{aligned} p_1 &= \Pr\left\{P_r^{harvest} \le P_r^{\max}\right\} \\ &= 1-\exp\left(-\frac{P_r^{\max}}{P_s^{\max}\beta_1}\right) \end{aligned} \tag{8}$$

$$\begin{aligned} p_2 &= \Pr\left\{P_r^{harvest} > P_r^{\max}\right\} \\ &= 1-p_1 \end{aligned} \tag{9}$$

The signal to noise ratio at the relay node during time (1-α)T/2 are given as

$$\gamma_{sr} = \frac{P_s^{\max} g_{sr}}{N_0 d_1^{\,m}} \tag{10}$$

and the signal to noise ratio at the secondary receiver is given as

$$\gamma_{rd_1} = \frac{P_r^{harvest} g_{rd}}{N_0 d_2^{\,m}} \quad \text{with probability } p_1 \tag{11}$$

$$\gamma_{rd_2} = \frac{P_r^{\max} g_{rd}}{N_0 d_2^{\,m}} \quad \text{with probability } p_2 \tag{12}$$

where 'd_2' is the distance between the relay and SU receiver.

In order to find the throughput of the SU, the ergodic capacity of source to relay link and relay to destination link is evaluated as

$$\begin{aligned} C_{sr}^{\,erg} &= E\{\log(1+\gamma_{sr})\} \\ &= \int_0^{\infty} \log(1+\gamma_{sr}) d\gamma_{sr} \\ &= -\exp(-\lambda_1) Ei(-\lambda_1) \end{aligned} \tag{13}$$

where $\lambda_1 = \frac{N_0 d_1^{\,m}}{P_s^{\max}}$ and $Ei(\mathrm{x})$ is the exponential integral function given by $Ei(x) = -\int_{-x}^{\infty} \frac{e^{-t}}{t} dt$ [14].

$$\begin{aligned} C_{rd}^{\,erg1} &= E\{\log(1+\gamma_{rd_1})\} \\ &= \frac{2N_0}{P_s^{\max}\beta_1} \int_0^{\infty} \log(1+\gamma_{rd_1}) f_{\gamma_{rd_1}}(\gamma_{rd_1}) d\gamma_{rd_1} \end{aligned} \tag{14}$$

where $\beta_1 = \frac{2\eta\alpha}{d_1^{\,m}(1-\alpha)}$.

Following [9], eq. (14) can be solved as

$$C_{rd}^{\,erg1} = -\frac{2N_0}{\beta_1 P_s^{\max} \log(4)} G_{p,q}^{m,n}\left(\begin{matrix} [\{0\},\{\ \}] \\ [\{-1,0,0\},\{\ \}] \end{matrix} \middle| \frac{N_0}{\beta_1 P_s^{\max}} \right) \tag{15}$$

$C_{rd}^{\,erg1}$: indicates the ergodic capacity of SR-SU receiver link when the relay works in harvest power mode i.e. mode 1 with probability p_1.

Here $G_{p,q}^{m,n}\left(\begin{matrix} a_1 \ldots . a_p \\ b_1 \ldots . b_q \end{matrix} \middle| z \right)$ indicates meijerG function is defined as [9]

$$\begin{aligned} &G_{p,q}^{m,n}\left(\begin{matrix} [\{a_1,\ldots,a_m\},\{a_{m+1},\ldots,a_p\}] \\ [\{b_1,\ldots,b_n\},\{b_{n+1},\ldots,a_q\}] \end{matrix} \middle| z \right) \\ &= \frac{1}{2\pi l} \int \frac{\prod_{j=1}^{m} \Gamma(1-a_j-s) \prod_{j=1}^{n} \Gamma(b_j+s)}{\prod_{j=m+1}^{p} \Gamma(a_j+s) \prod_{j=n+1}^{q} \Gamma(1-b_j-s)} z^{-s} ds \end{aligned} \tag{16}$$

where $l = \sqrt{-1}$ and $\Gamma(x) = \int_0^{\infty} t^{x-1} e^{-t} dt$ is the Gamma function.

Let $C_{rd}^{\,erg2}$ indicates the ergodic capacity of SR-SU receiver link when the relay works in underlay constrained mode i.e. mode 2 with probability p_2.

$$\begin{aligned} C_{rd}^{\,erg2} &= E\{\log(1+\gamma_{rd_2})\} \\ &= \int_0^{\infty} \log(1+\gamma_{rd_2}) f_{\gamma_{rd}^{\,2}}(\gamma_{rd_2}) d\gamma_{rd_2} \\ &= -\exp\left(\frac{N_0 d_2^{\,m}}{P_r^{\max}}\right) Ei\left(-\frac{N_0 d_2^{\,m}}{P_r^{\max}}\right) \end{aligned} \tag{17}$$

The actual ergodic capacity is given by minimum of source to relay and relay destination link ergodic capacity as [15].

$$C_1 = \min\left\{C_{sr}^{\,erg}, C_{rd}^{\,erg1}\right\} \text{ and } C_2 = \min\left\{C_{sr}^{\,erg}, C_{rd}^{\,erg2}\right\} \tag{18}$$

Overall ergodic capacity is given as

$$C_{ov} = p_1 C_1 + p_2 C_2 \tag{19}$$

Now the average throughput of the network is given as

$$\tau_{avg}^{\,erg} = p_1 \tau_1 + p_2 \tau_2 \tag{20}$$

where τ_1 and τ_2 are the throughput under transmit power of $P_r^{harvest}$ and $P_r^{\max}$ respectively and given as

$$\tau_1 = \frac{C_1(1-\alpha)T/2}{T} \text{ and } \tau_2 = \frac{C_2(1-\alpha)T/2}{T} \quad (21)$$

Also the average transmit power of relay is given as

$$P_{avg}{}^{r} = p_1 \overline{P}_r^{harvest} + p_2 P_r^{\max} \quad (22)$$

where $\overline{P}_r^{harvest}$ is the average transmit power when the relay is transmitting in harvest power mode i.e. mode 1.

$$\overline{P}_r^{harvest} = E_{g_{sr}}\left[\frac{\eta P_s^{\max} g_{sr}\alpha}{d_1{}^m(1-\alpha)}\right] = \frac{\eta P_s^{\max}\alpha}{d_1{}^m(1-\alpha)\lambda_{sr}} \quad (22)$$

where $1/\lambda_{sr}$ is the average channel gain between source to relay.

IV. Numerical And Simulation Result

A simulation test bed is developed in MATLAB to evaluate the performance based on the formulation provided. The following parameters are used in the simulation d_1=0.5,1, d_2=0.5,1, path loss exponent m=2.7and noise variance, N_0=1 .

In Fig. 3 throughput of SU is plotted against energy harvesting time for different value of I_{th}. It is observed that the throughput of the SU increases as the tolerable interference threshold increases. As I_{th} increases the allowable maximum transmit power of SU as well as relay increases which yields an improvement in throughput. With increase in α, harvested energy increases which increases the throughput, however beyond a certain α, further increase in α reduces transmission time of the relay causing throughput to reduce as seen in the Fig. 3.

Fig. 4 plots the throughput of the SU against energy harvesting time for several values of PU outage constraint ($\delta = 0.01, 0.05$). It is observed that the throughput of the SU improves as the allowable outage constraint of PU increases. An increase in δ allows SU as well as relay to increase its transmit power and thereby improves the throughput.

In Fig. 5, the transmission profile of relay is plotted against α for a given value of PU outage constraint (δ) and allowable interference threshold (I_{th}). As the energy harvesting time (α) increases, the probability of transmitting in harvesting mode decreases. As α increase, the maximum possible transmit power of the relay due to harvested energy increases and exceeds the maximum allowed power due to underlay constraint. This leads to switching of the transmit power of relay to underlay constrained power imposed by cognitive constraint i.e. power of underlay. Therefore probability of transmitting in harvested mode is reduces. Simultaneously the probability of transmitting at a power level corresponding to underlay constraint increases with increase in α.

In Fig. 6, the transmit power of relay in two modes i.e. harvest mode and underlay constraint mode is plotted against α. It is observed that the relay transmits in harvest mode and increases upto $\alpha = 0.3$ for $I_{th} = 5dB$ while the probability of transmitting in harvest mode decreases and hence the average transmit power of relay decreases. Further as α increases the relay switches to underlay constraint mode and transmit in that mode with constant power while the probability of transmitting in underlay constraint mode increases which yields increase in average transmit power of relay.

In Fig. 7, the average transmit power of relay is plotted against harvesting energy (α) for different value of δ. The average transmit power of relay increases as the allowable outage constraint of PU increases. An increase in δ means relay can increase its transmit power which yields in increase of average transmit power of the relay.

In Fig. 8, the average transmit power of relay is plotted against harvesting energy (α) for different value of I_{th}. The average transmit power of relay increases as the tolerable interference threshold increase. An increase in I_{th} means relay can increase its transmit power which yields in increase of average transmit power.

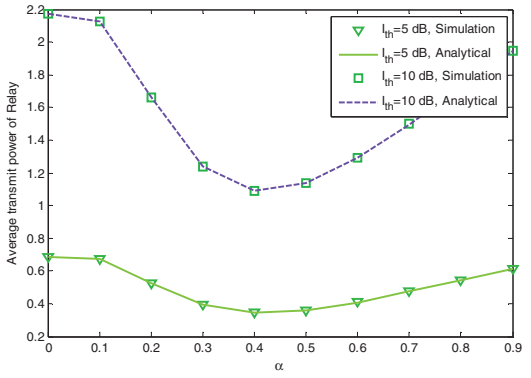

Fig. 8. Average transmit power of relay versus α for different value of PU outage constraint (δ=0.01).

V. CONCLUSIONS

In this paper the performance of cognitive relay network is evaluated under energy harvesting DF relay in terms of throughput. The impact of harvesting energy time, tolerable interference threshold, and allowable outage constraint of PU on the throughput of the system is evaluated. Furthermore the impact harvesting energy time, outage constrained and interference threshold on the average transmit power of SU relay is also indicated. It may be observed that there exists an optimal value of α which yields maximum throughput. The performance of SU improves as the allowable outage constraint of PU increases. Further the increase in allowable interference threshold also yields an improvement in throughput of SU.

***Abstract*—Cognitive radio (CR) enabled secondary users (SUs) identify the spectrum white spaces opportunistically. For accessing a channel in CR network, the SU require a medium access control (MAC) protocol to select a channel that can efficiently cover the total transmission time required for its data transmission. Many MAC protocols were developed for cognitive radio networks (CRNs), most of them have not considered the opportunistic transmission length of a primary user (PU) channel in order to rank the channels accordingly depending upon the probability of successful SUs transmission. Our proposed novel MAC protocol termed as *distributed token based medium access control* (DTMAC) will address the PUs channel usage pattern estimation as minimum opportunistic transmission length metric and distribution of tokens by every mesh router/access point according to the queue size of the SUs at that time instance. Access to the control channel is coordinated by packet overhearing mechanism to pass on the token fairly among the SUs. The proposed MAC simulated using the Network Simulator (ns-2), and the simulation results demonstrate that proposed protocol improved the performance compare to the existing protocols.**

Keywords: Multi Channel,Packet Overhearing,Multi Radio,Opportunistic Transmission,Tokens.

I. Introduction

Wireless mesh network is an emerged and promising technology, it provides low cost services up-to last mile. In order to achieve the reduction of equipment cost and demand of higher capacity, wireless mesh network(WMN) router devices will have several interfaces that work on multiple channels. In these kind of networks combining the channel allocation, interface assignment, and routing can efficiently improve the network capacity and basically related to the problem of efficient network resource allocation. A WMN which works with multiple-channels consists of number of stationary wireless mesh routers which forms a wireless backbone. Each router is equipped with multiple network interface cards (NICs) and every interface of the router can operate on a distinct frequency channel [1]. In WMN, the mesh routers (MR) serve as access points (APs) for wireless mobile devices [2].

A single-interface architecture limits the whole network to operate in a single channel. This is because the subset of nodes that are using one channel for communication get disconnected from the subset of nodes which are not using the same channel . In order to perform the cross-channel communication requires either channel switching functionality within each node or have to use multiple interfaces per node each tuned to operate in different channel. Cross-channel communication can be achieved by equipping each node with multiple interfaces each operating in different channel.

II. Related Work

Research in the development of MAC protocol for CR-WMNs is still in its infancy. Some of the works [5], [7], [10]–[14] which are already existing in the current literature. Peyman, Nasser, and Ahmad have developed the DT-MAC protocol in [3], they have developed a Dual-channel Token-based MAC (DT-MAC) protocol that can provide the scalability also improve the efficiency in the case of large number of users and at high physical rates. In this work the authors have used a multi-channel model with an common control channel and a data channel. The token has been exchanged to the node which have to transmit in the packets send through the control channel. The user who is having the token is privileged to use the data channel.

Ghazale and Nitin have proposed a Token-DCF MAC protocol in [4], which is an opportunistic MAC protocol for wireless networks. In this paper they have focused on a implicit token-passing mechanism in order to reduce the idle and collision times in current 802.11 DCF MAC protocol for the WLAN. In this paper their main aim is to design the MAC protocol in such a way that the transmitting station schedules one of its neighboring stations for the next transmission in a distributed manner. They have employed the packet overhearing mechanism which is a good inspiration for our work. The same authors have also proposed a overheard ACK with token passing MAC protocol in [5] which is an advancement to the work done by them for the Token-DCF MAC protocol in [4].

In this paper they have proposed a scheme called overheard ACK where explicit ACK frame has been removed using packet overhearing mechanism.Ali, A.; Piran, M.J.; Kim, H.; Yun, J.; Suh, D.Y have proposed a PU activity aware distributed MAC protocol in [6]. They have proposed licensed channel usage pattern identification scheme, based on a two state markov chain model and estimated the future idle slots using the previous observations of the channel.

III. Estimation of Opportunistic Transmission Length and Channel Ranking Algorithm

Following are the two research contributions made in this paper

1) We propose a multi-channel and multi-radio token based MAC in accordance to the cognitive radio wire-

less mesh architecture. In this architecture every mesh client/router/access point will have this MAC protocol in them and each have to sense the licensed channels for identifying any underutilized channels and analyze the usage patterns of those channels which belong to primary users for a specific period of time T_sam.

2) A novel channel assignment solution is proposed interms of channel ranking algorithm after collecting enough data related to usage patterns of all channels. The OTL metric calculation of every channel is estimated in terms of Min_OTL(Minimum Opportunistic Transmission Length),Max_OTL(Maximum Opportunistic Transmission Length).

A. Opportunistic Transmission Length (OTL) Metric Calculation

In Algorithm 1 the initial identifier value is provided TRUE for first time say $t = t_1$. Therefore for at $t1$, the $Min_OTL^c_{t_1}$ and $Max_OTL^c_{t_1}$ will be assigned the same values as the observed IT^c_t. From the next iterations we will consider the average of the monitored IT^c_t in addition to the previously calculated idle lengths $MinIL^c_{t_{i-1}}$ in accordance to the current situation which will reflect the respective change in the PU's activity while calculating the idle slots. Once the estimation of OTL's in respective frequency channels is done, SUs can use the licensed channels without causing harmful interference with the PUs. Then based on the continues PU's activity monitoring Min_OTL and Max_OTL values are calculated. The PHY-layer monitoring scheme will monitor the licensed channels usage patterns for a sufficient amount of time. After that based on the past observations its easy to predict when a channel is idle and if it is idle then for what amount of time it will be idle means for atleast the duration of its estimated Min_OTL.

While a dedicated radio monitors all the licensed channels say C (where $c = 1, 2, 3, 4, ..., N$) in a round robin fashion it will spend a short duration of $\Delta(T) = 1ms$ for each channel to detect its current state (idle or busy). It will continue for a time duration of $Tsam = 5sec$ to collect PU's traffic samples from all the channels.

During the channel monitoring, a channel c can go through four possible transitions which are as follows:

1) when channel c is found in ON state at time instance t_1 and when the same channel is found in again ON state at t_2 time instance then utilization time can be calculated as $UT = t_2 - t_1$.
$Ch(c, t_1) = ON \rightarrow Ch(c, t_2) = ON$,then UT^c_t, $UT^c_t = t_2 - t_1$
2) when channel c is found in ON state at time instance t_1 and when the same channel is found in OFF (means the detected energy level is below 1.16 db for the duration of T_{sam}) state at t_2 time instance then utilization time can be calculated as $UT = (t_2 - \lambda) - t_1$. (where λ is the detection error).
$Ch(c, t_1) = ON \rightarrow Ch(c, t_2) = OFF$,then UT^c_t, $UT^c_t = (t_2 - \lambda) - t_1$

Algorithm 1 Calculating the Expected Min_OTL and Max_OTL times

Input:IT^c_t,$MinIL^c_t$,$MaxIL^c_t$,$Flag$=$TRUE$,C=$\{c_1,..,c_n\}$ is set of channels
Output:$Min_OTL^c_t$,$Max_OTL^c_t$
begin
for $c \leftarrow c_1$ to N **do**
  $Min_OTL^c_{t_1} \leftarrow 0$
  $Max_OTL^c_{t_1} \leftarrow 0$
  for $i \leftarrow 2$ to T_{Sam} **do**
    if $Flag == TRUE$ **then**
      $MinIL^c_{t_i} \leftarrow IT^c_{t_i}$
      $MaxIL^c_{t_i} \leftarrow IT^c_{t_i}$
      $Flag = FALSE$
    else
      if $IT^c_{t_i} \leq MinIL^c_{t_i-1}$ **then**
        $MinIL^c_{t_i} = \frac{MinIL^c_{t_i-1} + IT^c_{t_i}}{2}$
      end if
      if $IT^c_{t_i} \geq MaxIL^c_{t_i-1}$ **then**
        $MinIL^c_{t_i} = \frac{MinIL^c_{t_i-1} + IT^c_{t_i}}{2}$
        $MaxIL^c_{t_i} = \frac{MaxIL^c_{t_i-1} + IT^c_{t_i}}{2}$
      end if
      if $IT^c_{t_i} > MinIL^c_{t_i-1}$ && $IT^c_{t_i} < MaxIL^c_{t_i-1}$ **then**
        $MinIL^c_{t_i} = \frac{MinIL^c_{t_i-1} + IT^c_{t_i}}{2}$
      end if
    end if
  end for
  $Min_OTL^c_{t_i} \leftarrow MinIL^c_{t_i}$
  $Max_OTL^c_{t_i} \leftarrow MaxIL^c_{t_i}$
end for

3) when channel c is found in ON state at time instance t_1 and when the same channel is found in again ON state at t_2 time instance then IdleTime(IT) can be calculated as $IT = t_2 - t_1$.
$Ch(c, t_1) = OFF \rightarrow Ch(c, t_2) = OFF$,then IT^c_t, $IT^c_t = t_2 - t_1$
4) when channel c is found in OFF state at time instance t_1 and when the same channel is found in ON state at t_2 time instance then IdleTime(IT) time can be calculated as $IT = (t_2 - \lambda) - t_1$.
$Ch(c, t_1) = OFF \rightarrow Ch(c, t_2) = ON$,then IT^c_t, $IT^c_t = (t_2 - \lambda) - t_1$

B. Expected Transmission Time Over a Channel

Lets consider the transmission time required for a current frame of user u as t_u. To fully use the spectrum opportunity, each SU calculates the probability of successfully transmitting the current frame over channel c [9], which can be given as

P^c_u = Pr(Channel c is idle, Transmission is successful)

$$= \frac{IT_c}{UT_c + IT_c} F_k(t_{AS_u} + t_u) \quad (1)$$

where UT_c and IT_c are the utilization and idle periods of channel c, respectively, t_{AS_u} is an arbitrary sensing period selected by user u, and t_u is the transmission time of the current frame, and $F_c(x)$ is the cumulative distribution function $F_c(x) = \left(\int_0^x f_c(x)\,dx\right)$ that characterizes the usage pattern of channel c by its PU's, the derivation can be found in [8]. As we have chosen for arbitrary sensing period, so SU's transmitting simultaneously and collide with each other. If no PU appears in $t_{AS_u} + t_u$ interval then transmission is successful.

After calculating the successful transmission probability of each channel, now the SU's can determine the channel sensing sequence by simple sensing the channel that is having highest success probability after arranging them in descending order to achieve low delay and high throughput. If a channel is very less occupied by PU's, then that channel will obviously be contented by more number of SU's and will leads to high contention among the SU's which are using the same radio resources and degrades the performance. Instead of using the above said sensing model, the secondary user can select a channel based on the QoS requirement of their application.

For an instance we can consider the maximum tolerable one hop delay τ_u. The τ_u is an average value of the successive round trip times say $T = \{t_1, t_2, t_3, t_4, t_5\}$ of the five packets sent on a specific channel say c. So the average of all these round trip times will be assigned to τ_u. If we know the P_u^c, the expected transmission time over channel c can be estimated as $E[T_u^c] = \frac{(t_{AS_u}+t_u)}{P_u^c}$. So the SU will select a group of channels that satisfies the below condition

$$E[T_u^c] = \frac{(t_{AS_u} + t_u)}{P_u^c} < \tau_u \tag{2}$$

The proposed channel ranking algorithm will rank the channels in accordance to the total utilization time and total idle time. Then after collecting all these channels which fall under this estimation condition in the given algorithm 2, it will then utilization factors of all the channels and arrange these values in descending order and select a channel with maximum utilization factor as rank 1, channel with second maximum utilization factor as rank 2 and so on for all the channels in set UF^c.

C. The Channel Assignment Problem

The IEEE 802.11 DCF access method is used in WLAN [4] in this protocol each and every time when a node want to send the data it have to contend for the channel, efficient MAC protocol but not scalable. The proposed MAC protocol is a multi-channel and multi-radio token based protocol. The main limitation with all the existing protocols is that they work with a control channel in order to exchange the information from the mesh router/access point like on which channel the node have to transmit the data. While one node is using the control channel for obtaining the information regarding the possible channels for data transmission, then the other node which want to use the same control channel when it senses that the channel is busy it will immediately go to DIFS amount of waiting time plus a random backoff time. So like this it will make the nodes go on waiting for their turn to get access to the control channel.

Algorithm 2 Channel Ranking Algorithm

Require: Utilization Time of Channels,Idle Time of Channels, Set of transmission times of every Packet in Queue,C=$\{c_1, c_2, c_3, ..., c_n\}$ is set of channels

Ensure: Rank of each channel c in accordance to the calculated UF^c

for $c \leftarrow 1$ to N **do**
  TUT^c=UT_{t1}^c
  TIT^c=IT_{t1}^c
  for $i \leftarrow 2$ to T_{Sam} **do**
    TUT^c=TUT^c+$UT_{t_i}^c$
    TIT^c=TIT^c+$IT_{t_i}^c$
  end for
  And then SU will collect all the channels that satisfy the condition in equation 2 as a set of estimated transmission time over channel c
  if $E[T_u^c] = \frac{(t_{AS_u}+t_u)}{P_u^c} < \tau_u$ **then**
    $Channel_Set$=Add this Channel c to the Collection
  end if
end for

Arrange the channels in set $Channel_Set$ in ascending order to select a channel with minimum P_u^c

for $c \leftarrow 1$ to $Channel_Set$ **do**
  ETT^c=$\frac{TIT^c}{TUT^c+\sum_{i=1}^{QS_t} t_i}$
  where t_i is the transmission time required for every packet in the queue
  UF^c=BOC_t^cxETT^c
end for
Arrange the utilization factors of all channels in set UF^c in descending order.

The main drawback with this is if a secondary user has more queue size of data to send then it will not have any priority, because as it is having more queue size of data to transmit. So if a node with less queue size next time gets the chance after contending for the control channel, another node with more queue size have to starve for its turn. In order overcome this problem we can simple use packet overhearing mechanism, so that the nodes which have more data to send will get the chance to access the channel first. Lets consider that there are three mesh clients/secondary users MC1,MC2,MC3 refer Figure 1 who want to get access to the control channel and lets assume that all of the mesh clients with in one hop distance will share their respective network layer queue sizes among them selves before performing any sort of data transmission. All the three will contend for the access to the control channel and only one among them will get the chance to access the control channel. Consider MC1 is the node who won access to the control channel and sent a request to the mesh router/access point requesting for a free channel availability by embedding

three fields of information

1) Current queue size
2) Next privileged mesh client among the MC2 and MC3 who have more queue size of data to send that particular mesh client will be given the access to the control channel
3) The channels that were sensed idle for a specific time by the MC1, this information is shared with the one hope access point/mesh router of MC1 (in the wireless mesh network, every mesh client will act as mesh router/access point to perform the multi-hop transmission of data).

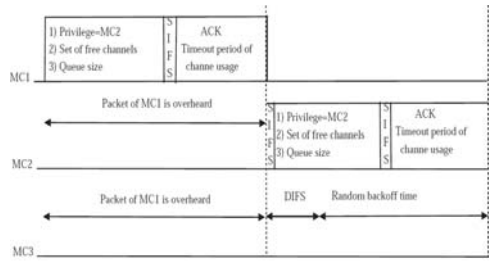

Fig. 1. Access Method of Multi-channel and Multi-radio MAC Protocol

The advantage with this kind of implicit token/privilege embedding mechanism is that, no need to send explicit token for passing the privilege of accessing the control channel to other mesh client which has more data to send in its queue. Because this control MAC frame which have been transmitted by MC1 previously will be overheard by the remaining mesh clients and they will update the queue size of MC1 in there queue size table which is maintained by every mesh client/mesh routers. After every successful access to the control channel by a mesh client, the mesh client which have received the privilege no need to go back and wait for DIFS and some random backoff time. The mesh client which have got the privilege to access the control channel will start its immediate transmission of data by just waiting for a short period of SIFS. With this it will reduce the idle time and increase the throughput of the network by implicitly transmitting the token/privilege inside the MAC header of the data packets transmitted over the control channel. The other mesh clients who don't have privilege will automatically fall back to normal 802.11 DCF mode of operation means they will wait for DIFS+Random Backoff time, so that we can reduce the collisions between the mesh clients at maximum rate.

The mesh router/access point sends request to one hop neighbors, if it receives a request for the access to a free channel depending on the queue size added to the MAC header of the data packets it will selects the channel that best suits according to the queue size requirements of the MC1 and send the best channel for data transmission from the MC1 to the access point if the destination node is in different network or a best channel for data transmission from the MC1 to the destination itself if the designated node is with in the reach of the MC1.

This channel along with the time up-to which that channel is available for transmission information is embedded in the ACK which is returned by the mesh router/access point to MC1.The need to maintain the information regarding time upto which that channel is available for transmission is considered. As the PU can't wait more than Max_OTL time, within the duration SU must be find other channel to switch. The Min_OTL gives the estimated time up-to which the allocated channel for transmission will be available without degrading the QOS provided to a primary users (PU's). So once Min_OTL expires, then the mesh router/access point which have allocated the channel will fix that channel as a free channel in its Channel Usage Table(CUT).

IV. Performance Evaluation

We will measure the performance of our MAC protocol with respect to estimated Min_OTL and Max_OTL of the primary users and SU's throughput while transmitting the data. Simulation results are performed by writing extensive C code. Figures 2 and 3 represent the observed Min_OTL and Max_OTL of the 5 licensed channels of primary users. Here the secondary users will transmit the data atleast for a minimum time of Min_OTL time. From these two graphs we can see how the values change very often due to the change in the activity of the primary users in there respective channel usage pattern. So with these two values we can estimate upto how much time for sure a SU can transmit the data without any collisions.

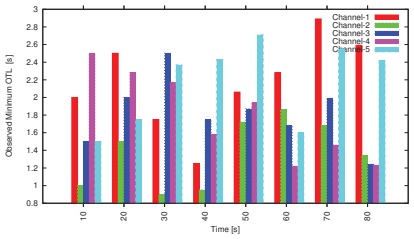

Fig. 2. Observed minimum opportunistic transmission length(OTL)

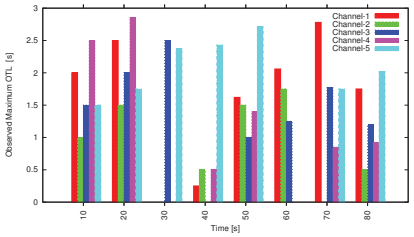

Fig. 3. Observed maximum opportunistic transmission length(OTL)

The simulations for DTMAC and PAD-MAC[6] are done in NS-2 to measure and compare the performance of these two MAC protocols. The network is a wireless cognitive radio mesh network in which the transmitting stations i.e., the secondary users are placed uniformly at random in a square area (150mx150m). The population of primary users is

considered in different numbers for every single execution of the simulation which lasted for 1020 seconds each. In each run, a different topology is considered. In our simulation by using the proposed channel ranking algorithm its possible to achieve grater throughput rates as we increase number of primary users and secondary users in the successive runs of the simulation.

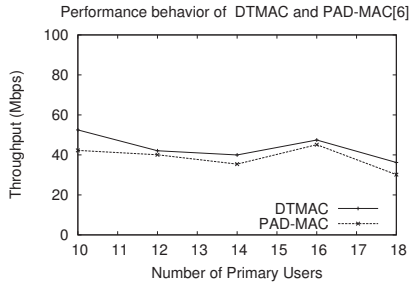

Fig. 4. Aggregate throughput (area=150mx150m)

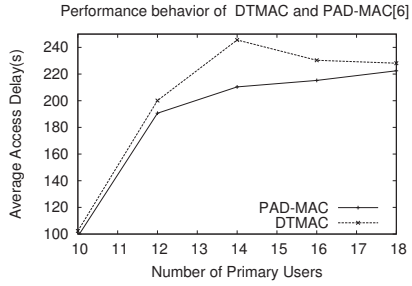

Fig. 5. Average access delay (area=150mx150m)

The aggregate throughput of PAD-MAC and DTMAC is presented in Figure 4. It can be seen that the throughput gained by DTMAC is a factor 1.2 to 1.5. Figure 5 shows the average access delay of the two protocols. It is the delay incurred between the packet at which the packet arrives at MAC layer and time at which source of the packet receives acknowledgment from the destination. It consists of the waiting time before transmitting on the channel and the time spent in packet retransmissions. Here you can see that packet delay is much smaller in DTMAC when compared to PAD-MAC. The reason is that DTMAC have much smaller idle times when compared to PAD-MAC. As a result many retransmissions are avoided my reducing the collisions.

V. Conclusion and Future Work

Our main focus in designing this MAC was on estimating the idle times of each and every channel that a secondary users/mesh clients and the mesh routers/access points can sense. And after calculating the minimum opportunistic transmission length of all the channel using the utilization and the idle time values. We have derived the equation for estimation of the channels that can be feasible for allocating to a SUs transmission. After that we have represented with an instance how the distributed token based multi-channel and multi-radio MAC protocol helps to avoid collisions among the secondary users and also how it reduces the idle and starvation times among SU's when the same control channel is accessed by multiple SU's. In the future work we will design a channel assignment and routing based distributed MAC protocol which considers the channel capacity as a metric to assign channels to SU's.

Abstract— **The proposed Swastika Slot UWB (SS-UWB) patch antenna designed specifically for body-worn applications in Wireless Body Area Networks (WBAN). Ultra-wideband (UWB) technology, standardized by IEEE 802.15.6 TG-6 for ultra-low power consumption, is one of the fastest growing technologies for short range communications. The increasing demand of compact size, portable, body-worn, and lightweight electronic devices for the WBAN applications requires the design of miniature antennas. Therefore, in this paper, we present a SS-UWB, which covers the frequency spectrum from 3.45 – 13 GHz [9.65 GHz] with a gain varied from 2.3 – 5.87 dB and total antenna efficiency varied from -0.76 to -2.67 dB (91.6% – 73.6%) over free space. Also, in this paper, we investigate the effect of antenna-body gap in terms of reflection coefficient, gain, and total antenna efficiency in free space and modeled phantom. Most importantly, we have also analyzed the effect of specific absorption rate (SAR) over modeled human phantom due to interactions between human body and the antenna.**

Keywords- Wireless Body Area Networks (WBAN), Body-worn antennas, Ultra-wideband (UWB), Specific absorption rate (SAR), Antenna efficiency.

I. INTRODUCTION

The body-worn antenna and body-centric communication systems has received much attention over the past few years for healthcare monitoring applications. Such systems are gained much concern for other applications like sports and fitness, gaming, lifestyle and entertainment [1]. Advances in microelectronics and wireless communications have enabled a way to make small and lightweight monitoring devices which consumes less (ultra-low) power. Such intelligent monitoring devices can be equipped together to configure Wireless Body Area Networks (WBAN). WBAN gather information on entities of interest by multiple distributed sensor elements, placed in, on or around human body to monitor the health condition pervasively and ubiquitously [2]–[3]. The requirements of high bandwidth with low power consumption are the key concerns for the wearable healthcare monitoring systems and applications. Since the low power consumption will significantly increases the life of battery driven devices. Therefore, the requirement of extremely low power became the necessity of such application.

Ultra-wideband (UWB) technology, standardized by IEEE 802.15.6 TG-6, is the fastest anticipating technology for such short range communications system [4]. With a very low range of effective isotropic radiating power (EIRP) emission density, less than -41.3 dBm/MHz, longer battery life for wearable and implanted health monitoring devices can be achieved. Moreover, the lesser EIRP value results in low level of interference which allows it to coexist with other system. Also it provides resistant against multipath and potential application dependent higher data transmission rate varies from few Kbps to Mbps.

Designing antenna for WBAN has several critical issues, one such issue is presence of human body in the near-field that can significantly affect antenna's performance [5]–[6]. One of the most critical issues is the size of the antenna for portable devices. Reducing antenna's size leads to various problems due to performance disfavours in antenna characteristics, such as impedance mismatch, radiation efficiency, and bandwidth. Therefore, it is quite challenging task to design a miniature antenna, which should capable of providing wide bandwidth and have reasonable performance in the vicinity of human body for impedance matching with acceptable gain.

Much exhaustive research activity has been employed on wearable antenna design and their performance modeling in presence of human body [7]–[11]. In [12], authors shown that antenna time domain characteristics are significantly improve due to presence of lossy human body.

In this paper, we have analyzed the antenna's performance in free space and in direct contact to layered human body phantom. The main objective is to study the nature of dispersive human tissues and their electrical properties, and how the antenna parameters are changed by means of the antenna-body gap. Moreover, we have performed a parametric study to observe the effects of various dimensional (notches, slot, feed width and feed gap) parameters in order to optimize antenna performance. The rest of paper is as follows. The modified SS-UWB patch antenna design and parametric study are given in section II. Section III provides the discussions related to measured and simulated results. Finally in section IV, we present conclusions of results and the future course.

II. ANTENNA DESIGN

The proposed geometry and the fabricated prototype of SS-UWB patch antenna are shown in Fig. 1.(a) and 1.(b). The reduced dimension of the antenna is 27 x 27 x 1.6 mm^3 as compared to 30 x 30 x 1.6 mm^3 in [13]. The patch and ground plane are placed on opposite sides of dielectric substrate (FR-4) having permittivity of 4.4 and loss tangent of 0.025. The radiating patch of size 13.5 x 11 mm^2 is fed by a microstrip line of width 2.8 mm. The two notches size of 1.5 x 1.5 mm^2 and 1 x 1 mm^2 are at the two bottom corners of the radiating patch. The feed gap between patch to the ground plane is 1 mm. The length of ground plane is 10.5 mm. The proposed swastika slot is printed on top of radiating patch of size 3.5 x 3.5 mm^2. Simulations of this antenna have been done by using ANSYS High Frequency Structure Simulator (HFSS) [14].

A. *Effect of the Notches at the bottom of Radiating Patch*

Fig. 2(a) and 2(b) shows the two step notches of dimensions 1.5 x 1.5 mm^2 and 1 x 1 mm^2 respectively at the bottom of patch. In addition, swastika slot with two step notches at the center of patch is shown in Fig. 2(c). Such notching techniques have been utilized for better capacitive tuning between ground plane and lower part of antenna, resulting to achieve wider impedance bandwidth.

As shown in Fig. 3, the reflection coefficient of antenna with 2 steps notches cutting at the bottom of radiating patch with swastika slot, the S_{11} curve is best, covering the frequency range from 3.45 GHz to 13 GHz. The two steps notch at bottom of patch provides a good matching bandwidth with the more peak values of reflection coefficient. While one step notch provides less matching bandwidth covers the frequency range of 6.1 GHz to 13.45 GHz.

Table I shows the effect of two notches and swastika slot at the bottom and centre of patch respectively to the antenna bandwidth. The basic rectangular patch 13.5 x 11 mm^2 ($W_P \times L_P$) provides the fractional bandwidth of 67.18%. This fractional bandwidth increases to 75.2% by cutting one notch at the bottom, while this fractional bandwidth further increases to 109.37% by cutting two notches at the bottom of patch.

Moreover, a fractional bandwidth of 116.11% is achieved by cutting swastika slot at the center of patch along with two notches at the bottom of patch. Hence, the proper selections in the size of notches and slot can lead to different UWB performance characteristics.

TABLE I.
THE EFFECT OF NOTCHES TO THE SIMULATED -10 dB BANDWIDTH OF PROPOSEED ANTENNA

Notches	f_L (GHz)	f_U (GHz)	Absolute BW (GHz)	Fractional BW (%)
0	4.35	8.75	4.4	67.18
1	6.1	13.45	7.35	75.2
2	3.75	12.8	9.05	109.37
2 & SS	3.45	13	9.55	116.11

Fig. 2. Step notches at the bottom of patch and swastika slot at center of patch a) 1 step notch b) 2 steps notches c) 2 steps notches with swastika slot at the center of patch

B. *Effect of the Feed Gap*

The feed gap between the lower edge of the patch and the ground plane is given essential effect to the impedance bandwidth. The partial ground plane on the bottom of the substrate acted as an impedance matching element. The authors were taken four different values of feed gap of 0.5, 1, 1.5, and 2 mm in order to determine the optimum size of feed gap.

Fig. 4 shows the simulated reflection coefficient (S_{11}) curves for different feed gaps to the ground planes of SS-UWB antenna. It is shown in Fig. 4 and Table II that the -10 dB bandwidth of antenna varies with the variation of the feed gaps. The optimal feed gap from simulated result is found to be 1 mm with the fractional bandwidth of 116.11 %.

It can be clearly depicted from Table II that the -10 dB bandwidth of SS-UWB antenna does not deviate much with the variation of feed gaps below 1.5 mm. But when the feed gap value increases from 1.5 mm, it will degrade the impedance bandwidth performance. These simulated results show the dependency of antenna impedance bandwidth on feed gaps of the ground plane. Thus, the ground plane acts as the impedance matching element.

TABLE II.
SIMULATED -10 dB BANDWIDTH OF PROPOSEED ANTENNA FOR DIFFERENT FEED GAP

Feed Gaps (mm)	f_L (GHz)	f_U (GHz)	Absolute BW (GHz)	Fractional BW (%)
0.5	3.7	13.7	10	114.9
1	3.45	13	9.65	116.11
1.5	3.4	12.2	8.8	112.8
2	3.75	11.35	7.6	100.66

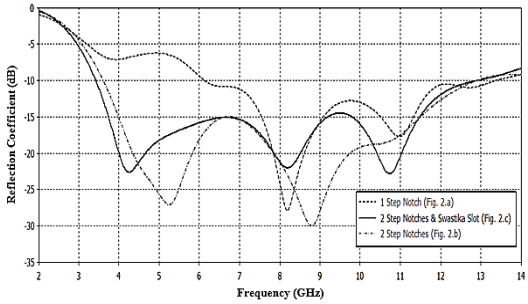

Fig. 3. Simulated S_{11} curves of various steps notches with swastika slot

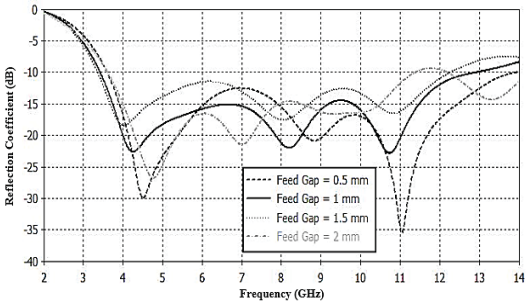

Fig. 4. Simulated S_{11} curves of proposed antenna for different feed gaps

C. *Effect of Feed Width*

Fig. 5 shows the simulated reflection coefficient curves of the proposed antenna. The authors were taken five different values of feed width of 2.6 mm, 2.8 mm, 3 mm, 3.2 mm, and 3.4 mm in order to determine the optimum size of feed width. It is shown in Fig. 6 that the -10 dB bandwidth of antenna varies with the variation of the feed widths. It can be clearly visualized that the lower edge of frequency bandwidth is quite independent of the feed widths variations, while upper edge of frequency bandwidth is much dependent on different feed width variations.

III. RESULTS AND DISCUSSIONS

In this section, we present the results obtained from full-wave electromagnetic solver. The performance of antenna was measured over free space and over modeled dispersive layered human phantom as in [15]. The antenna-body gap is introduced by using foam substrate having permittivity of 1.067, loss tangent of 0.0041. The main objective of introducing antenna-body gap is to analyze the interactions between human tissue equivalent model and the antenna. Also, this spacing is useful towards to avoid the hazardous EM absorption in soft human tissue. We examined the antenna performance over different antenna-body gaps values in the range of 0-10 mm.

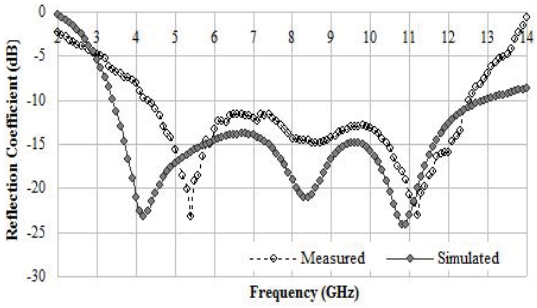
(a)



(b)

Fig. 6. Measurement of fabricated Swastika slot UWB antenna a) The VNA setup and b) Measured vs. simulated S_{11} curves

A. *Reflection Coefficient (S_{11})*

Fig. 6 shows the reflection coefficient measurement setup on L-Vector Network Analyzer (Agilent PNA series) and the measured vs. simulated S_{11} curve, respectively. In this prototype, a 50 Ω SMA connector is soldered at bottom edge of microstrip feed line which is further connected to VNA by an RF coaxial cable. The measured -10 dB bandwidth for the S_{11} results in range from 4.25 to 12.5 GHz, which is close to the simulated range from 3.45 to 13 GHz. The obtain result is acceptable; however, there is a shift of 0.8 GHz between the simulated and the measured S_{11} result at lower frequency. This shift is mainly due to the inevitable fabrication error and the amount of soldering used to attach the feeding pin. The RF cable has also some significant affects over the antenna performance. In addition, we were not taken the effect of mismatch in the simulation due to the adapter and connector used. Also, there is a slight difference between the actual dielectric properties used in the fabrication and the one used in the simulation.

B. *Radiation Pattern*

The high directivity antennas are desirable in WBAN as well as in UWB wireless communications. Since, the high value of directivity at a specific angle will lead to minimize power consumption and energy absorption within the body and most importantly minimize the path loss [16]–[17]. Fig. 7 shows the polar plot of radiation patterns (E_θ field) of the SS-UWB antenna for different antenna-body gap values.

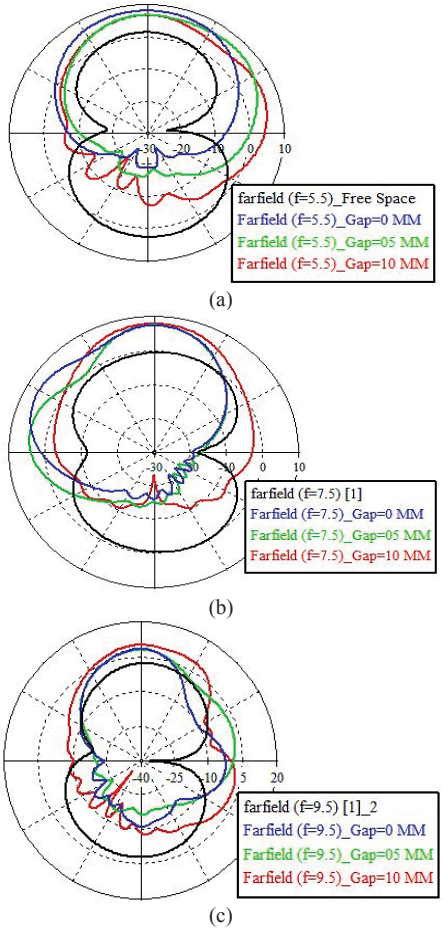


Fig. 7. The polar plot of radiation patterns of Swastika Slot antenna over modeled layered human phantom over different gap value at: a) 5.5 GHz, b) 7.5 GHz, and c) 9.5 GHz

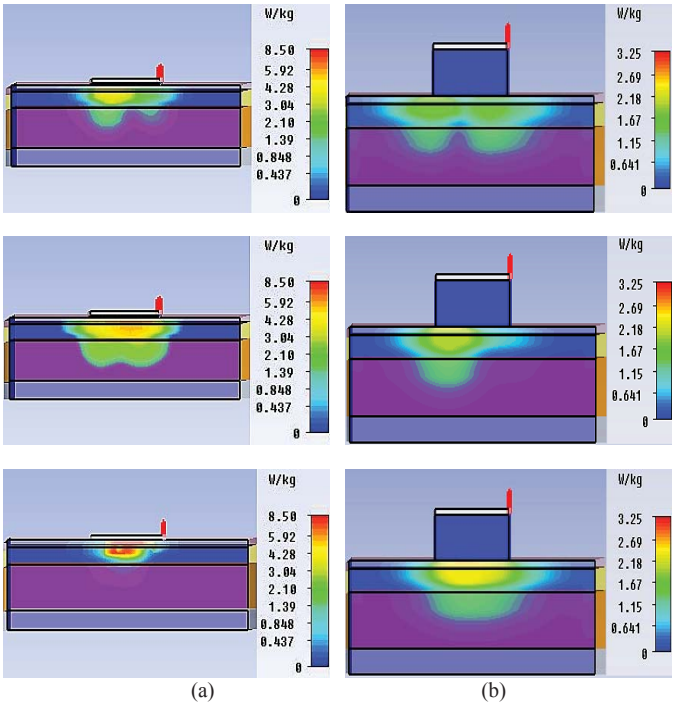

Fig. 8. SAR levels over 1g mass average layered human phantom without gaping and with 10 mm gaping at a) 5.5 GHz b) 7.5 GHz and c) 9.5 GHz

C. *Specific Absorption Rate (SAR)*

Fig. 8 shows the simulated SAR levels over layered phantom with and without antenna-body gap at frequencies 5.5 GHz, 7.5 GHz and 9.5 GHz respectively. All simulation has been done over 1g mass averaged SAR of human tissue defined as a tissue volume in the shape of cube. We observed peak SAR level of 6.26, 7.66 and 8.29 W/kg respectively over layered phantom without gaping substrate [15]. While much lower SAR values of 0.884, 0.994 and 1.54 W/Kg respectively has been observed at mentioned frequency with 10 mm antenna-body gap.

The summarize SAR results were listed in Table V. From the result, we observed that as frequency and tissue thickness increases, the SAR value also increases. The main cause for such incident is high conductivity (σ) and permittivity (ϵ_r) of skin and muscle layer, which causes severe impedance mismatch between them. That's why the fat layer possesses much absorbed power density. Also the high electric field ($\vec{E}$) value governs higher SAR value since it is related to electric field as

$$SAR = \frac{\sigma}{\rho}\vec{E}^2 \quad (1)$$

TABLE III.
SIMULATED PEAK SAR LEVEL OVER PHANTOMS

Frequency (GHz)	SAR (W/Kg) Layered Phantom without Gap (1g mass average)	SAR (W/Kg) Layered Phantom with Foam (1g mass average)
5.5	6.26	0.884
7.5	7.66	0.994
9.5	8.29	1.54

D. *Maximum Gain and Total Antenna Efficiency*

Fig. 9 shows the simulated maximum gain and total antenna efficiency over free space and over modeled phantom. From Fig. 9.(a), we can clearly depict that the deterioration of the maximum gain was occurred when antenna placed in direct contact (antenna-body gap=0 mm) to phantom. This is due to the presence of lossy human body. The antenna gain varied from 2.4 – 5.87 dB, over free space. However, the maximum gain having value of 8.43 dB has been achieved, when we increased the distance between antenna and body to the value of 10 mm. Furthermore, a constant gain of 7 dB has been observed throughout the frequency span with a 10 mm gap over modeled phantom. This is due to the reflection from the highly lossy human body tissue and the material (foam) utilized for gaping. Moreover, the maximum gain of proposed SS-UWB antenna has not increases with further increment in the antenna-body gap. Similarly, we observed that the total antenna efficiency, as shown in Fig. 9.(b), is significantly deteriorated, when antenna placed in direct contact with human tissue-equivalent phantom. Though, the highest antenna efficiency of value -0.76 dB (91.6%) has been achieved with the 10 mm antenna-body gap, which is very close to the free space efficiency. In conclusion, both the antenna gain and total antenna efficiency deteriorated close to

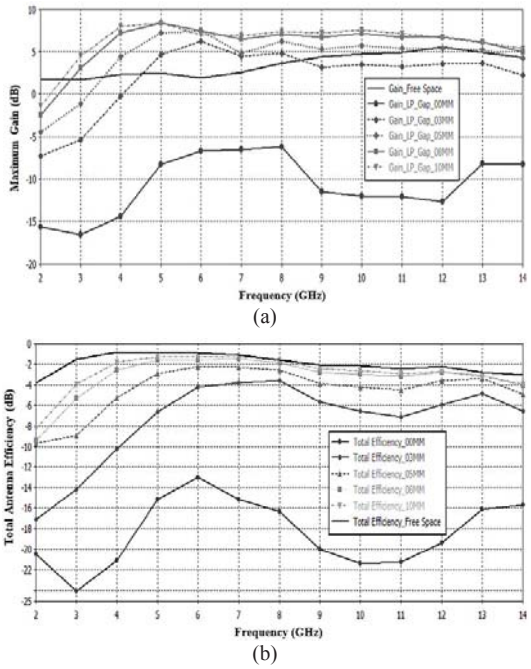

Fig. 9. Simulated a) Maximum gain, and b) Total antenna efficiency

the modeled human tissue equivalent phantom. Also, from these results, the directivity of antenna is maximum when antenna operated close to the human phantom.

IV. CONCLUSION

In this research endeavor we have investigated the performance of SS-UWB patch antenna over frequency range of 3.45 GHz – 13 GHz for antenna-body gap values of 0-10 mm. The efficiency of this design has been established by investigating the effect of antenna-body gap on the performance of antenna at three different frequencies: 5.5 GHz, 7.5 GHz and 9.5 GHz respectively. The fabricated SS-UWB antenna exhibits the wider impedance bandwidth ranging from 4.25 to 12.5 GHz over free space.

The maximum antenna gain of 5.87 dB has been achieved over free space, while a much better gain of 8.43 dB has been achieved when antenna placed at 10 mm gap. Moreover, the total antenna efficiency varied from 73.6% (-2.6 dB) to 91.6% (-0.76 dB) in the mentioned frequency span. However, a constant efficiency close to - 1 dB (89.13 %) has been achieved over frequency range from 3.1 – 7 GHz, than after deterioration in antenna efficiency (goes up to – 2.6 dB) has been observed. Also the S_{11} curve varies from -15 dB to -22 dB in the frequency range of 3.8 – 11.5 GHz.

Furthermore, most of the significant antenna results have been observed at antenna-body gap of value above 5 mm. Also, variation in the thickness of different human tissue may affect the antenna performance especially in terms of impedance mismatch. We need to study the design in different human system to modify the antenna design towards a more realistic one in application. Then it would generate a comprehensive solution to the present day wearable sensing and computing communication devices.

***Abstract*—In this paper the physical layer security of an underlay Cognitive Relay Network (CRN) based on wireless energy harvesting (EH) relay is studied. We consider a decode and forward (DF) relay node harvests energy from radio frequency (RF) signal transmission of secondary user (SU). We evaluate the Secrecy Outage Probability (SOP) of secondary relay network assuming that the channel state information (CSI) of the interfering links from both the SU and relay transmitter to PU receiver are imperfect. The transmit power of the SU as well as relay is controlled by the maximum tolerable interference at PU because of underlay environment and outage constraint of PU as demanded by quality of service (QOS) of PU. The impact of maximum tolerable interference threshold, energy harvesting time, imperfect CSI, and PU outage constraint on the secrecy outage of the SU network is also investigated.**

Keywords— Imperfect channel state information (CSI); Secrecy Outage Probability (SOP); Cognitive Relay Network (CRN); Energy Harvesting (EH).

I. INTRODUCTION

In the recent year there has been phenomenal growth in the field of wireless communication system which increases the demand for radio spectrum resource. Furthermore as reported by FCC, the utilization of some spectrum band is as low as 15% in the band below 3 GHz resulting in spectrum underutilization. Cognitive radio has evolved as an efficient means to strike a balance between spectrum scarcity and spectrum underutilization [1]. Underlay spectrum sharing is one of the potential techniques used to access the licensed spectrum allocated to the primary user (PU). In underlay approach, SU accesses the same band as used by the PU concurrently provided the interference produced due SU transmission is within a tolerable interference threshold limit of PU [2]. As the transmit power of SU is controlled in order to protect the PU in underlay spectrum sharing technique, the performance of SU is limited. Cooperative relay technique is one of the potential techniques used to enhance the system performance in terms of spatial diversity. A combination of cognitive radio and cooperative diversity is used to enhance the performance of Cognitive Relay Network (CRN) in terms of coverage area [3-4]. In the case of an energy constrained network, the performance is limited due to energy constraint of the relay. In the recent year wireless energy harvesting is advocated to enhance the part of energy constrained network. An energy harvesting DF relay has been analyzed where the relay is assumed to harvest energy from the RF source [5-6]. However cognitive radio networks face new privacy and security threat due to broadcast nature of wireless channel. Thus security is one of the utmost importance in this type of networks [7]. The customs way of security is based on cryptographic approaches but physical layer security is an appealing approach to achieve secured transmission [8] which gained a considerable attention over last few years. In the wiretap model introduced by Wyner [9], the source and destination try to communicate reliably while an eavesdropper tries to snoop the confidential message. Depending on the channel conditions and the bad intention of eavesdropper, a secrecy rate may not be achievable which leads to secrecy outage. Secrecy outage can be explained as a service condition and it happens when a desired secrecy falls below a threshold of acceptable performance. Using this secrecy outage parameter we can say how much securely we can forward our confidential information to the destination. This paper investigates physical (PHY) layer security in a CRN in presence of an eavesdropper. In an underlay network, SU needs to adjusts its transmit power so as to maintain a maximum interference threshold tolerable at the PU receiver. It requires the CSI of the SU transmitter and PU receiver be available at the SU transmitter. However due to practical limitations, perfect CSI may not be available at SU transmitter**.** Outage performance of a cognitive relay network with imperfect channel knowledge estimations has been analyzed in [10] without considering the security issues. A general cooperative network based on decode and forward relaying has been studied in [11] where the relay is assumed to harvest energy through the RF transmission from the source with time switching based relaying. Throughput of energy harvesting based relaying scheme is analyzed in [11] without any focus on security issues. In the present work we analyze the physical layer security in terms of SOP of an underlay cognitive relay network, where a cognitive relay harvests energy from the RF transmission of the secondary user and the CSI available at the secondary user as well as relay is imperfect. Further a QOS of the primary user in terms of maximum allowed interference threshold and an outage constraint is maintained. The major contribution of this paper can summarized as below:

- An analytical formulation is presented to evaluate SOP for an underlay CRN using a wireless energy harvesting relay in presence of imperfect CSI.
- Impact of primary QOS in terms of maximum allowable interference at primary receiver and a constraint on primary outage on SOP is evaluated.

- Impact of imperfection in CSI and energy harvesting time on SOP is indicated.
- Further, outage probability and intercept probability of SU relay is formulated for the considered network.
- A simulation test bed in MATLAB is developed following our analytical model to assess the performance of the network in terms of secrecy outage probability (SOP) of the secondary user.

The rest of this paper is organized as follows: Section II describes the system model of an underlay CRN with imperfect CSI at secondary user and relay in presence of an eavesdropper. In Section III, we derive the expression of secrecy outage probability of SU under imperfect CSI and constraint of PU QOS. Results on SOP, based on our formulation, are presented in Section IV. Finally, Section V concludes the paper.

II. SYSTEM MODEL

An underlay Cognitive Relay Network model consisting of a SU transmitter (SU-Tx), a secondary relay (SR), a SU destination (SU-Rx), an eavesdropper (Eav) and a PU receiver (PU-Rx) is considered in this paper as shown in Fig. 1. We assume that there is no direct link between SU-Tx and SU-Rx node. Thus an intermediate relay working in DF mode assists the secondary transmission. Secondary relay tries to send confidential information reliably to the destination, SU-Rx while an eavesdropper (Eav) tries to snoop that confidential information. We consider that channel state information (CSI) of the interference links i.e. both SU-Tx to PU-Rx and relay transmitter to PU-Rx are imperfect. The relay harvests energy from the signal transmitted by secondary user and uses the harvested energy as a source of transmit power as outlined in the Time Switching–Based Relaying(TSR) scheme of [11] . Further the SU as well as the relay attempts to maintain interference produced at PU-Rx below the interference threshold. The relay is assumed to harvest energy for a fraction of time (αT) of the total time frame T and the half of remaining time i.e. (1-α)T/2 is used for source to relay information transmission while the other half, (1-α)T/2 for relay to destination information transmission as shown in Fig.2. The relay is assumed to perform the joint task of energy harvesting and information processing [12]. The transmit power of SU-Tx and relays are controlled so as to maintain an outage constraint of PU-Rx. The harvested energy is used by the relay as a source of transmit power, ($P_r^{harvest}$) to send the information from relay to SU-Rx. However there are two cases for the level of transmitted power from relay such as (i) if the maximum possible transmit power based on harvested energy ($P_r^{harvest}$) is less than the maximum allowed transmit power (P_r) due to outage constraint of PU, the relay transmits with power $P_r^{harvest}$, otherwise (ii) if the maximum possible transmit power based on harvested energy($P_r^{harvest}$) exceeds P_r, the transmission power of the relay is limited to P_r. All the channels links $(h_i, i \in \{sr, sp, rd, re, rp\})$ are assumed to be independent and identically distributed Rayleigh fading channel with zero mean and unity variance i.e. $h_i \sim CN(0,1)$. The corresponding channel gains denoted as $g_i = |h_i|^2, i \in (sr, sp, rd, re, rp)$ are exponentially distributed. In a practical case, it is very difficult to acquire perfect CSI in a CRN due to mobility, feedback delay and channel estimation errors. Thus in most of the practical cases available CSI is imperfect. Therefore, following imperfect channel a model of as in [13], the estimated channel coefficient is given as follows:

$$\hat{h}_{sp} = \rho h_{sp} + \sqrt{1-\rho^2}\,\varepsilon \quad (1)$$

$$\hat{h}_{rp} = \rho h_{rp} + \sqrt{1-\rho^2}\,\varepsilon \quad (2)$$

Where h_{sp}, h_{rp} denotes the ideal channel coefficient and $\hat{h}_{sp}, \hat{h}_{rp}$ are the channel estimation available at the SU-Tx and SR respectively, ε is a Gaussian Random variable with zero mean and variance one and is uncorrelated with h_{sp}, h_{rp}. The correlation coefficient ρ $(0 \le \rho \le 1)$ is a constant that determines the average quality of the channel estimation over all channel states which reflects the degree of imperfections of CSI estimations. For example, if $\rho = 1$, the channel knowledge is perfect and the full CSI is available, while $\rho = 0$ means that CSI estimation is completely random. The estimated channel power gains $\hat{g}_{sp}$ and $\hat{g}_{rp}$ are exponentially distributed with mean λ_{sp} and λ_{rp} respectively as $g_{sp} = |h_{sp}|^2, g_{rp} = |h_{rp}|^2$.

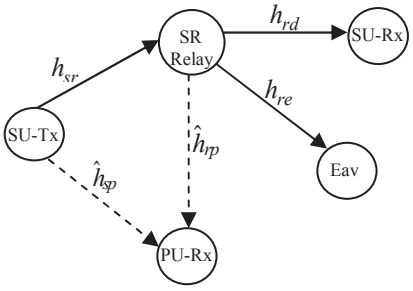

Fig. 1. System model for Cognitive Relay Network.

III. SECRECY OUTAGE PROBABILITY(SOP) OF ENERGY HARVESTING RELAY

The SOP of the CRN is analyzed where energy harvesting relay harvests energy using the time switching scheme. The transmission block arrangement in the time switching based relaying scheme as in [11] is shown in Fig. 2. Here T is the transmission block time for transmitting information from Su-Tx to SU-Rx. α indicates the fraction of T in which time the relay harvests energy from SU-Tx and uses it as a source of transmit power at relay to forward the information during time (1-α)T/2 maintaining an outage constraint on PU.

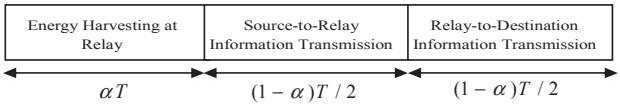

Fig. 2. Transmission block structure for energy harvesting and information transmission.

The energy harvested by the relay over a time of αT , considering a normalized distance between SU_Tx and SR as units,is given as [14].

$$E_h = \delta P_s g_{sr} \alpha T \tag{3}$$

where $0 < \delta < 1$ is the energy conversion efficiency and depends on the energy harvesting circuitry [14] and P_s is the SU transmit power. Using harvested energy E_h as a source of power for (1-α)T/2 time, the maximum transmitted power from the relay node can be written as,

$$\begin{aligned} P_r^{harvest} &= \frac{E_h}{(1-\alpha)T/2} \\ &= \frac{2\delta P_s g_{sr} \alpha}{(1-\alpha)} \end{aligned} \tag{4}$$

As explained earlier that there are two cases for the level of transmitted power from relay which is given as

$$P_{relay}^{Tx} = P_r^{harvest} \quad if\ P_r^{harvest} \le P_r \tag{4.1}$$

$$= P_r \quad if\ P_r^{harvest} > P_r \tag{4.2}$$

It may be noted that when the relay transmits as per (4.1), we call it transmission in harvesting power mode while in the case the, transmission is governed as per (4.2), we call it transmission in interference constrained mode. However it may be noted that in both the cases the transmission energy is derived from the harvested transmission energy only.

Because of imperfect CSI of the interference links from both SU-Tx to PU-Rx and SR to PU-Rx the transmit power of SU-Tx and SR are governed as below:

$$p_s = \frac{\eta P_{th}}{\hat{g}_{sp}} \quad \text{and} \quad p_r = \frac{\eta P_{th}}{\hat{g}_{rp}} \tag{5}$$

Thus equation (5) defines the maximum instantaneous transmit power of SU and SR. where η is a scaling parameter $(0 < \eta \le 1)$ used to limit the transmit power of SU and SR taking into account the effects of imperfect CSI. Further 'η' is chosen appropriately so as to maintain a constraint on primary user outage. In order to protect the PU-Rx from harmful interference of the SU-Tx and SR, the instantaneous transmit power of SU-Tx must be controlled so as to maintain a given constraint (θ) on outage probability of PU as given by [15].

$$\begin{aligned} P_{out}^{pu} &= \text{Prob}\{p_r g_{rp} > P_{th}\} \le \theta \\ &= 1 - \frac{1}{2}\left(1 + \frac{1-\eta}{\sqrt{(1+\eta)^2 - 4\rho^2\eta}}\right) \le \theta \end{aligned} \tag{6}$$

The above equation is valid for $(0 \le \rho \le 1)$ and $(0 < \eta \le 1)$ .The possible value of η for a given ρ is obtained by equating $P_{out}^{pu} = \theta$

$$or,\ 1 - \frac{1}{2}\left(1 + \frac{1-\eta}{\sqrt{(1+\eta)^2 - 4\rho^2\eta}}\right) = \theta \tag{7}$$

Now we evaluate the probability (p_1) and probability (p_2) of transmitting in harvesting mode and interference constraint mode respectively as given below.

$$\begin{aligned} p_1 &= \Pr\left\{P_r^{harvest} \le P_r\right\} \\ &= \Pr\left\{\frac{g_{sr}}{\hat{g}_{sp}} < \frac{1-\alpha}{2\alpha\delta} \cdot \frac{1}{\hat{g}_{rp}}\right\} \\ &= -\frac{1-\alpha}{2\alpha\delta}\exp\left(\frac{1-\alpha}{2\alpha\delta}\right) Ei\left(-\frac{1-\alpha}{2\alpha\delta}\right) \end{aligned} \tag{8}$$

Where $Ei(\mathrm{x})$ is the exponential integral function given by $Ei(x) = -\int_{-x}^{\infty} \frac{e^{-t}}{t} dt$ [16].

Similarly

$$\begin{aligned} p_2 &= \Pr\left\{P_r^{harvest} > P_r\right\} \\ &= 1 - p_1 \end{aligned} \tag{9}$$

Now the channel capacity of SR to SU-Rx link i.e. destination channel, is given as:

$$C_{rd} = p_1 \log_2(1+\gamma_{rd1}) + p_2 \log_2(1+\gamma_{rd2}) \tag{10}$$

Where, γ_{rd1} and γ_{rd2} are signal to noise ratio at the SU-Rx considering two different modes of relay transmit power with probabilities p_1 and p_2 respectively as given by

$$\gamma_{rd1} = P_r^{harvest} g_{rd} \tag{11}$$

$$\gamma_{rd2} = P_r g_{rd} \tag{12}$$

Here we are assuming that the noise power is normalized.

Similarly channel capacity of relay to eavesdropper link, is given as:

$$C_{re} = p_1 \log_2(1+\gamma_{re1}) + p_2 \log_2(1+\gamma_{re2}) \tag{13}$$

where γ_{re1} and γ_{re2} are SNR at the eavesdropper for two different modes of relay transmit power with probabilities p_1 and p_2 respectively as given by

$$\gamma_{re1} = P_r^{harvest} g_{re} \tag{11}$$

$$\gamma_{re2} = P_r g_{re} \tag{12}$$

The secrecy capacity C_S is expressed as, [17],

$$C_S = (C_{rd} - C_{re})^+ \tag{14}$$

Where, $[x]^+ = \max\{x, 0\}$

In presence of eavesdropping, if $C_S > R_S$ then perfect secrecy is achieved. Where, R_S is the target secrecy rate. Otherwise, in the case of $C_S < R_S$, secrecy is compromised meaning occurrence of secrecy outage. Now secrecy outage probability (SOP) can be defined as the probability that the instantaneous secrecy capacity, C_S is less than a target secrecy rate, R_S which can now be expressed as,

$$\begin{aligned} SOP &= prob[C_S \le R_S] \\ SOP &= \left(SOP_{harv}\ p_1\right) + \left(SOP_{cogn}\ p_2\right) \end{aligned} \tag{15}$$

$$SOP_{harv} = \int_0^{\infty}\int_0^{\infty} prob\left[C_s^h \le R_S\right] f_{g_{rd}}(g_{rd})\, f_{g_{re}}(g_{re})\, dg_{rd}\, dg_{re}$$

$$SOP_{cogn} = \int_0^{\infty}\int_0^{\infty} prob\left[C_s^c \le R_S\right] f_{g_{rd}}(g_{rd})\, f_{g_{re}}(g_{re})\, dg_{rd}\, dg_{re}$$

Where $f_{g_{rd}}(g_{rd})$ *and* $f_{g_{re}}(g_{re})$ are the pdf of g_{rd} *and* g_{re} respectively.

$$C_s^c = \log_2 \frac{1+\gamma_{rd1}}{1+\gamma_{re1}} \text{ And } C_s^h = \log_2 \frac{1+\gamma_{rd2}}{1+\gamma_{re2}}$$

where, C_s^h is the secrecy capacity when relay transmits in harvesting mode and C_s^c is the secrecy capacity when relay transmits in cognitive constraint mode.

Equation (15) represents SOP of an energy harvesting relay under imperfect CSI in cognitive relay network.

In addition to secrecy outage probability, intercept probability (IP) is also used to characterized the security performance of a network [18]. Further reliability performance of the network is indicated by Outage Probability (OP) [18].

Now we provide the necessary analytical expressions developed to evaluate the outage probability and probability of intercept for the network with energy harvesting relay under study. Outage probability (OP), P_{out} is defined as the probability that the capacity of source-destination (SD) link (C_{rd}) falls below a target data rate, R_d [18].

$$P_{out} = prob\left[C_{rd} < R_d\right]$$

$$= \int_0^\infty p_1\ prob\left[C_{rd} < R_d\right] f_{g_{rd}}(g_{rd})\, dg_{rd} + \int_0^\infty p_2\ prob\left[C_{rd} < R_d\right] f_{g_{rd}}(g_{rd})\, dg_{rd} \quad (16)$$

Similarly the intercept probability (IP) P_{int} is defined as the probability that the capacity of source to eavesdropper link (C_{re}) exceeds a target data rate, R_d [18].

$$P_{\text{int}} = prob\left[C_{re} > R_d\right]$$

$$= \int_0^\infty p_1\ prob\left[C_{re} > R_d\right] f_{g_{re}}(g_{re})\, dg_{re} + \int_0^\infty p_2\ prob\left[C_{re} > R_d\right] f_{g_{re}}(g_{re})\, dg_{re} \quad (17)$$

The IP and OP are used to characterize the security and reliability of the network under study. We evaluate the impact of imperfect CSI and other network parameters on IP and OP

IV. Simulation Result

We develop a MATLAB based simulation test bed on basis of our formulation to evaluate secrecy outage, intercept probability, outage probability. We now present our simulation results. Following parameter values are used in our simulation, target secrecy rate R_S =0.5 kbps/Hz, target data rate R_d =0.5 kbps/Hz, energy conversion efficiency δ =1, PU outage constraint θ =1%, 3% and 5%.

Fig.3 depicts the SOP w.r.t energy harvesting time (α), for several values of interference threshold power (P_{th}). Initially for lower and moderate values of α, we have $p_1 > p_2$ which indicates that the relay has higher probability of being in harvesting mode. With gradual increase in α, the relay is able to harvest more energy which increases the transmit power of the relay and reduces SOP gradually. However beyond a certain optimum value of α (= 0.5 in the present case), we have $p_2 > p_1$, indicating that the relay switches to cognitive constraint mode with higher probability, where its transmit power is adjusted maintaining the interference constraint. This results in dominating component of eq(15) i.e. SOP_{cogn} remains invariant w.r.t α and higher values of dominating p_2 leads to increase in overall SOP.

Fig.4 represents the effect of P_{th} on intercept probability of the eavesdropper link for several values of PU outage constraint (θ). Higher values of P_{th} allows the relay to transmit at higher power which increases the capacity C_{re}. This leads to an increase in IP. Similarly increase in θ also increases transmission power SU which in turn increases P_{int}.

Fig.5 shows the variation of outage probability of relay to SU-Rx link with interference threshold power, (P_{th}) for three different values of outage probability constraint of PU e.g. (θ =1%,3%,5%). Higher values of P_{th} allows SU-Rx to transmit at higher power which leads P_{out} to fall gradually. At a fixed P_{th}, if we increase θ i.e. SU-Tx is allowed to transmit at higher power level, P_{out} gradually reduces.

Fig.6 shows the variation of secrecy outage probability (SOP) of EH relay with interference threshold power, P_{th} for three different values of channel correlation coefficient, (*i.e.* ρ = 0.2, 0.5 and 0.8) and two values of energy harvesting parameters (α). Higher interference threshold allows SU transmitter to transmit at a higher power level. This leads SOP to gradually reduce as we increase the interference threshold which allows the relay to transmit at a higher power level. Further SOP reduces with higher ρ for a given level of P_{th} i.e. as CSI estimation moves towards a perfect case, SOP reduces. The joint impact of P_{th} and ρ on SOP is evident from this figure. It may be noted that for chosen value of $\alpha = 0.4$, the probability of transmitting in harvesting mode by the relay is more i.e. $p_1 > p_2$, which implies that we are operating in left part of the optimum value of α in Fig.3.

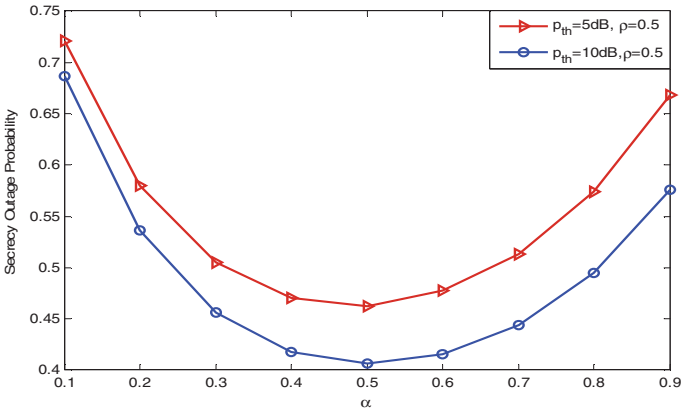

Fig. 3. SOP against α for different values of interference threshold power P_{th} (i.e. P_{th} =5,10 dB)where consider ρ = 0.5

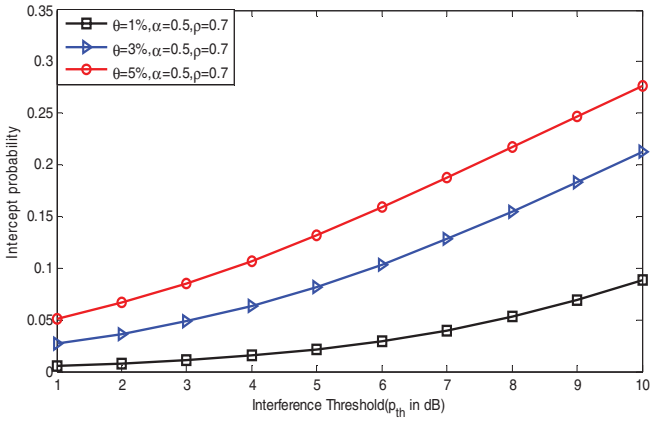

Fig. 4. Intercept probability versus P_{th} in dB for different values of PU outage constraint, θ (*i.e.* θ =1%,3%,5%) where consider R_d=0.5kbps/Hz

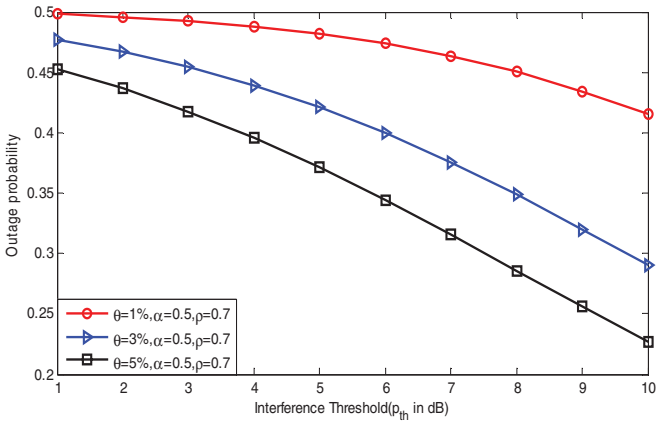

Fig. 5. Outage probability versus P_{th} in dB for different values of PU outage constraint, θ (*i.e.* θ =1%,3%,5%) where consider R_d=0.5kbps/Hz.

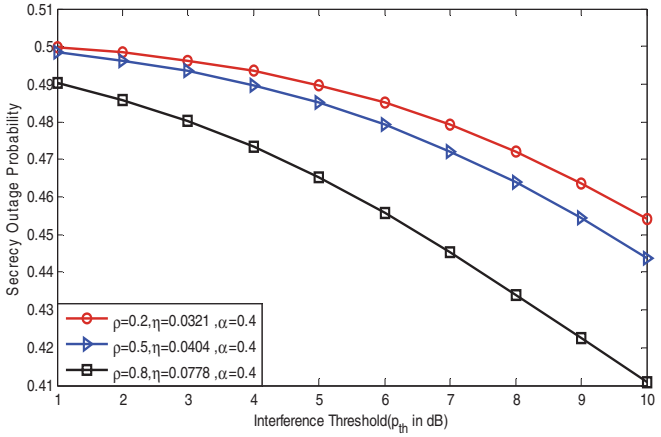

Fig. 6. SOP versus P_{th} in dB for different values of channel correlation coefficient, ρ (*i.e.* ρ =0.2, 0.5 and 0.8) for R_S=0.5 kbps/Hz.

V. CONCLUSION

An analytical model of an underlay cognitive relay network using an energy harvesting relay with imperfect CSI of the interfering links at secondary user and relay in presence of an eavesdropper is presented. The impact of QOS of PU on secrecy outage of energy harvesting based secondary relay is evaluated. The impact of harvesting time parameter in Time Switching Relay (TSR) scheme on secrecy outage is also indicated. Furthermore, the maximum tolerable interference at PU_Rx, maximum allowed outage of PU as well as imperfect CSI have significant effects on SOP. Higher interference threshold, as well as higher outage probability constraint increases intercept probability and reduces outage probability. An optimal energy harvesting time is observed which minimizes secrecy outage probability.

***Abstract*—TV white-space (TVWS) communication systems have been globally researched and developed due to its wide frequency range and superior propagation characteristics. In addition, EIRP +36 dBm is permitted as the maximum transmission power for fixed devices in some operational rules regulated in the U.S.A., the U.K., etc., and thus, the TVWS has been strongly expected to allow a long-haul backbone network at relatively low cost. On the other hand, rigorous RF characteristics such as adjacent channel power leakage are required for the WS devices not to interfere with primary users and there are some challenges in prototyping WS devices enabling high output power in conformity to such regulations. In this study, WS devices based on IEEE 802.11af communication system with a maximum output power of +30 dBm at the antenna port have been prototyped. The prototyped devices conform to the ETSI draft specification and are licensed by the Ofcom for the TVWS pilot program. Field experiment in the London urban area was also performed and resulted in a UDP throughput of about 2.2 Mbit/s with a line-on-site distance of about 3.7 km. From this result, it was confirmed that the TVWS communication system indicated the possibility of the long-haul backbone network even in a metropolis.**

Keywords—TV white-spaces (TVWS); IEEE 802.11af; high power; long-haul backbone network; field experiment

I. INTRODUCTION

The UHF band mainly allocated to TV broadcasters has possibility to provide a long-haul backbone network at low cost due to its relatively wide frequency range and superior propagation characteristics in comparison with frequency bands assigned to existing commercial networks. Therefore, white-spaces in the TV band (TVWS, TV White-Spaces) are expected not only for further accommodation of rapid-increasing mobile traffic but also for provision of broadband access in a rural area. Besides, the TVWS is also expected for the deployment of a new backbone network in the future smart city even in an urban area. For such social implementation, some international communication systems, e.g. IEEE 802.15.4 [1], IEEE 802.11af [2] and IEEE 802.22 [3], have been standardized and some rules for secondary use of the TVWS have been established in some countries such as the U.S.A. [4], the U.K. [5], Singapore [6]. In these regulations, an output power of EIRP +36 dBm is permitted as maximum transmission power for fixed devices and has boosted utilization of the TVWS for the long-haul backbone network. Furthermore, field experiment for deployment of the infrastructures utilizing the TVWS has been performed in some other countries as one of solutions for the bridge of the digital divide [7],[8].

On the other hand, rigorous RF characteristics, especially the leakage in the entire TV band outside a using channel, are required to avoid interference with the primary users such as TV broadcasters and wireless microphones. WS devices must comply with these requirements and there are still some challenges to develop hardware prototypes that are capable of transmitting a high-power RF signal with reasonable size and cost.

In this study, the authors developed hardware prototypes based on IEEE 802.11af system with the capability of transmitting a high output power of +30 dBm at the antenna port. These prototypes were licensed by the Ofcom (Office of communications) in conformity to the ETSI (European Telecommunications Standards Institute) draft specification that was adopted as a regulation in the U.K. The authors also developed TVWS communication systems including the WS database (WSDB) that also conformed to the Ofcom requirement, and participated in the TVWS pilot program operated by the Ofcom. In this trial, field experiment as a feasibility study of a long-haul backbone network was performed in London urban area and a UDP throughput of about 2.2 Mbit/s was obtained with a line-on-site distance of about 3.7 km.

The rest of this paper is organized as follows. The pilot program organized by the Ofcom in the U.K and required specification regulated by the ETSI are described in Section II and III, respectively. The prototyped device is described in Section IV and its RF performance is characterized in Section

This research was conducted under contract of R&D on “dynamic spectrum access in multiple frequency bands for efficient radio resource utilization" with the Ministry of Internal Affairs and Communications, Japan.

V. Then, the result of the field experiment in London urban area is summarized in Section VI. Finally, we conclude this paper with Section VII.

II. TVWS Pilot Program in U.K.

In the U.K., a 320 MHz frequency range from 470 MHz to 790 MHz is assigned to the DTT (Digital Terrestrial TV) and divided into 40 channels with an 8 MHz bandwidth. In addition, PSME (Programme Making and Social Events) services such as wireless microphones are operated in the TV band and permitted to preferentially utilize unused DTT channels. Therefore, secondary systems need to operate in cooperation with the WSDB to find available channels and WS devices are required to comply with the draft specification regulated by the ETSI to prevent the interference with the primary systems.

A. System Requirement

Fig. 1 shows an overview of the secondary system with the WSDB in the U.K. The interface between WS device and WSDB is properly determined and the WSDB needs to be authenticated by the Ofcom. Here, WS devices are classified into two types: *Master Device* and *Slave Device*. Before starting the communication in the TVWS, *Master Device* has to access a WSDB listing server operated by the Ofcom and acquire a list of WSDBs. Then, *Master Device* selects one WSDB from the list for parameters exchange and informs the selected WSDB of geo-location, antenna height and device parameters including *Device Emission Class*. After receiving the parameters, the WSDB calculates and provides available channels with each permitted maximum output power. After that, *Master Device* selects optimal channel to utilize and starts beacon transmission to *Slave Device.* The beacon includes permitted maximum output power, and thus, *Slave Device* optimally set its radio parameters according to the received parameter information. Eventually, *Slave Device* answers *Master Device*, and then TVWS communication is started.

During the operation in the TVWS, *Master Device* should access the WSDB and update the available channel list at least every 15 minutes, since PSME services are operated intermittently in various locations and status of available channels is frequently changed, especially in urban areas such as central London. For the WSDB, the operational schedule of the PSME service is reflected in up to 15 minutes before starting its operation. In the case that the PSME service starts to occupy the using channel of the secondary system, the secondary users must stop their operation or change the using channel to other available one. Furthermore, *kill switch* function, which allows emergency stop of the secondary system under the Ofcom's operation, must be implemented in both WSDB and WS device.

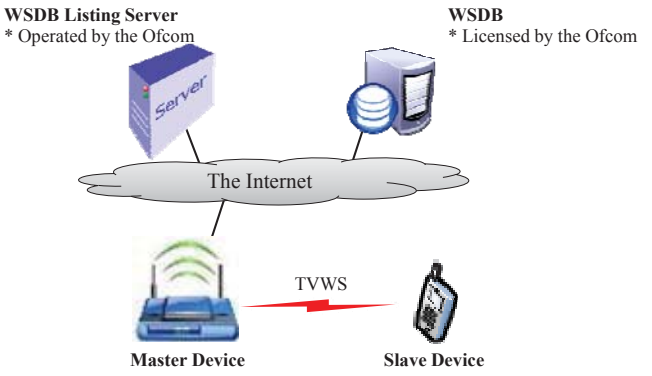

Figure 1. Overview of TVWS communication system in pilot program in the U.K.

B. Performance Requirement

Requirement for WS devices is regulated in the ETSI draft specification [9]. Particularly, adjacent channel leakage power is important to prevent the interference with primary users and stipulated as a relative value with the output power in the using DTT channel by following.

$$P_{OOB}\,(\text{dBm}/(100\ \text{kHz})) \le \max\{\,P_{IB}\,(\text{dBm}/(8\ \text{MHz})) - ACLR\,(\text{dB}),\ -84\,(\text{dBm}/(100\ \text{kHz}))\,\}, \quad (1)$$

where P_{OOB} is leakage power in a 100 kHz bandwidth outside the using channel and P_{IB} is output power in a 8 MHz BW of the using channel. Here, the *ACLR* (Adjacent Channel Leakage power Ratio) is defined by the suppression ratio of P_{OOB} to P_{IB}. Table I shows *ACLR* requirement in the ETSI draft specification and WS devices are classified into 5 *Device Emission Classes*, i.e. device classes, according to the ACLR performance. As above-mentioned, WS devices inform the WSDB of its device class before starting the TVWS communication and receive an available DTT channel list with permitted maximum power for each channel from the WSDB. At that time, availability of the TVWS varies by the device class.

III. High Power Prototype based on IEEE 802.11af

Fig. 2 shows an appearance of the prototyped WS device enabling a high output power of +30 dBm at the antenna port, based on IEEE 802.11af communication system. Overall size is 190 mm ×150 mm × 64 mm, including cooling fins. The prototype mainly consists of 6 boards as shown in Fig. 3; an I/O board for management of power supply and peripheral devices, a CPU board in which upper-layer MAC (Media Access Control) is implemented, an FPGA board for baseband processing, a DC/DC board for providing power to RF circuit, an RF board for main RF circuits including an AD/DA circuit and a transceiver IC and an high power amplifier (HPA) board for transmitting high output power. An external antenna is connected via an SMA connector implemented to the housing. According to the channel assignment of DTT in the U.K., the frequency setting of the prototype corresponds to an 8 MHz

TABLE I. ACLR for Different Device Emission Classes [9]

Where P_{OOB} falls within *n*th adjacent DTT channel	ACLR (dB)				
	Class 1	*Class 2*	*Class 3*	*Class 4*	*Class 5*
$n = \pm 1$	74	74	64	54	43
$n = \pm 2$	79	74	74	64	53
$n \ge +3, n \le -3$	84	74	84	74	64

interval.

Fig. 4 shows a block diagram of an RF part. In this prototype, direct conversion system is applied with using off-the-shelf RF IC. In the transmission part, the HPA that enables a high output power of +30 dBm is implemented with a pre-distorter circuit to reduce a distortion generated by the HPA. In the reception part, a wide-band low noise amplifier (LNA) is implemented and a variable attenuator is inserted to adjust received signal level to an acceptable level for the commercial RF IC. An RF switch is used to connect both transmission and reception circuits to the antenna port and a band pass filter (BPF) with a pass-band of 470−870 MHz is inserted between the RF switch and the antenna port to suppress unwanted signals such as harmonics in the transmission signal and image signals for the receiver circuit.

Table II shows the RF specification of the prototyped WS device. A supporting frequency range is limited to 500−710 MHz, due to the difficulty in a design of a wide-band amplifier that allows high output power in the entire TV band. In consideration of insertion loss of the BPF and the RF switch between the HPA and the antenna port, a +33 dBm output power is required for the HPA to support a +30 dBm output power at the antenna port in conformance with the ETSI draft standard. Furthermore, since at least 10 dB back-off is required to support OFDM (Orthogonal Frequency-Division Multiplexing) system in IEEE 802.11af standard, the HPA needs to support a peak output power of more than +43 dBm in the entire TV band. In the prototype, pre-distorter is implemented to suppress a distortion generated by the HPA, however, there are some challenges to sufficiently compensate the distortion in a wide frequency range of 470−790 MHz mainly due to insufficient frequency characteristics of matching circuits.

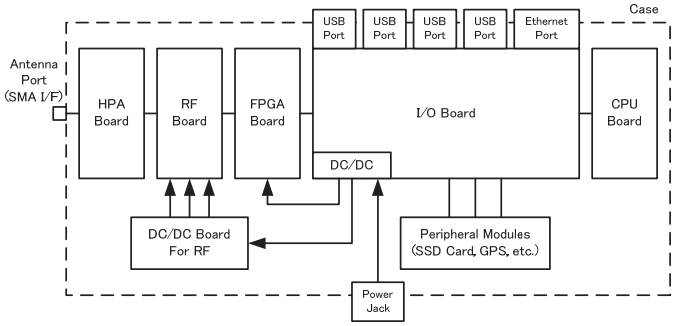

Figure 3. Hardware architecture of prototyped WS device.

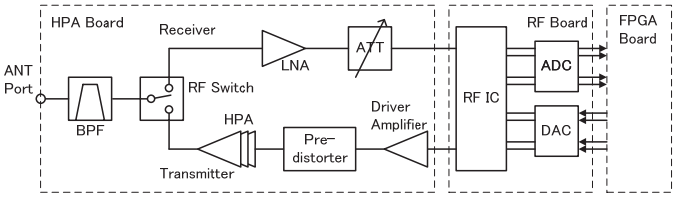

Figure 4. Block diagram of RF part.

TABLE II. RF SPECIFICATION OF PROTOTYPED DEVICE

Item	Description
Communication system	IEEE 802.11af
Supporting frequency range	500−710 MHz
Resolution of frequency setting	1 MHz
Frequency accuracy	±2 ppm
Output power	+30 dBm
Tuning range of output power	> 40 dB
Receiver dynamic range	−88 − −20 dBm

IV. RF PERFORMANCE

In this study, RF performance of the prototyped device was measured in conformity to the ETSI draft specification. Table III shows typical measured RF characteristics. All the measurement result except for *RIM3* followed measurement procedure described in the ETSI draft specification [9].

A. Transmission Power

In the ETSI draft specification, measurement procedures are stated as following. First, output power in the entire DTT band is measured by using a calibrated power meter. Then, transmission spectrum is measured by spectrum analyzer (SA) in the conditions of Table IV. All the measurement data are added together and compared with the measurement result by power meter to compensate transmission spectrum measured by SA. For instance, in the case that summation of the measurement data by SA is 1 dB higher than the result by power meter, each measured data by SA should be 1 dB reduced. After compensation of all the measurement data by SA, summation in the using DTT channel with an 8 MHz bandwidth is calculated as P_{IB}. Also, spectrum density in 100 kHz bandwidth and P_{OOB} are calculated by adding up 10 series data in each 100 kHz bandwidth. As a result of that, P_{IB} of +26.1 dBm is obtained at a center frequency of 682 MHz with a setting power of +27 dBm. Here, a 3-element ring Yagi antenna with a 7.6 dBi directivity is used in the after-mentioned field experiment, and thus, total transmission power is set to EIRP +34.7 dBm, not exceed an permitted maximum output power of EIRP +36 dBm. All other measurement results satisfy the ETSI draft specification in this measurement conditions.

TABLE III. RF CHARACTERISTICS OF PROTOTYPED WS DEVICE

Item	Conditions	Unit	Spec	Measured
Center freq.		MHz	–	682
P_{IB}	+28 dBm setup	dBm/ 8 MHz	–	26.1
Spectrum density		dBm/ 100 kHz	–	10.6
ACLR	n=−1	dB	≥43	63.2
	n=+1	dB	≥43	65.2
	n=−2	dB	≥53	73.0
	n=+2	dB	≥53	76.3
	n≤−3	dB	≥64	72.1
	n≥+3	dB	≥64	75.7
Transmitter unwanted emission outside TV band	30−47MHz	dBm/ 100 kHz	≤−36	−60.4
	47−74MHz		≤−54	−58.9
	74−87.5MHz		≤−36	−60.3
	87.5−118MHz		≤−54	−60.3
	118−174MHz		≤−36	−60.7
	174−230MHz		≤−54	−60.4
	230−470MHz		≤−36	−44.3
	790−862MHz		≤−54	−59.3
	862−1,000MHz		≤−36	−57.7
	1−4GHz	dBm/ 1 MHz	≤−30	−37.0
Transmitter intermodulation (RIM)	Lower	dB	≥45	71.7
	Upper	dB	≥45	76.0
Receiver spurious emissions	30MHz−1GHz	dBm/ 100 kHz	≤−57	−80.2
	1−4GHz	dBm/ 1 MHz	≤−47	−61.4

B. ACLR

As described in Section II, ACLR is calculated from P_{IB} and P_{OOB} measured in previous sub-section. Fig. 5 shows a typical spectrum mask in 682 MHz. Dotted line shows a limitation of the P_{OOB} calculated from the measured P_{IB} and ACLR requirement for Class 5 devices. From this result, signal level outside the using channel is sufficiently lower than P_{OOB} limitation in the entire TV band and the spectrum mask complies with the ETSI draft specification.

C. Unwanted Emissions and Intermodulation

Transmitter unwanted emissions outside the TV band and receiver spurious emissions comply with the ETSI draft specification as shown in Table III.

Transmitter intermodulation is measured by using a typical measurement system as shown in Fig. 6, in lieu of the measurement system in [9]. In this measurement, a WS device, a signal generator (SG) for unwanted signal generation and an SA are connected to each other through a power divider. Transmission frequency of the WS device is set to f_w and output power is set to maximum output power in Table III. Unwanted signal with a frequency of f_{un} is input from the SG and its signal level of P_u is set to –10 dBm, even though unwanted signal level is defined to 40 dB lower than transmission signal level in the ETSI draft specification. During the measurement with this setup, 3rd intermodulation with a signal level of *PIM3* is observed at a frequency of $2 \times f_w - f_{un}$ on the SA. Then, the third-order reverse intermodulation attenuation of *RIM3* is calculated by substitution of P_{IB}, P_u and *PIM3* to the following equation.

$$RIM3 = 2 \times P_{IB} + P_u - PIM3. \quad (2)$$

The prototypes were licensed by the Ofcom with a confirmation of these measurement method and result.

TABLE IV. MEASUREMENT CONDITIONS FOR TRANSMISSION POWER

Setting Item	Conditions
RBW (Resolution Band Width)	10 kHz
VBW (Video Band Width)	30 kHz
Start Frequency	470 MHz + RBW/2
Stop Frequency	790 MHz – RBW/2
Trace Mode	Max hold
Detector	RMS

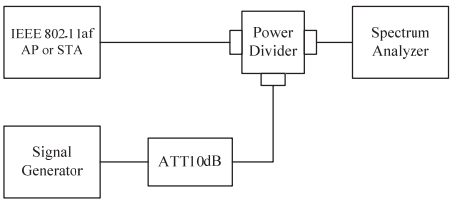

Figure 6. Measurement system for transmitter intermodulation.

V. FIELD EXPERIMENT IN LONDON

A. IEEE 802.11af-based Communication System

Field experiments in London urban area were performed with 2 prototyped WS devices; an access point (AP) and a station (STA). Fig. 7 shows overview of the communication system based on the IEEE 802.11af standard for the field experiments. The AP is connected to the RLSS (Registered Location Secure Server) installed in Japan via the Internet, and accesses the WSDB listing server operated by the Ofcom through the RLSS. Then, available channel list is obtained. After the AP selects some utilizable channels in the list according to the device performance and user's requirement,

the AP inform the RLSS of selected channels. Then, the RLSS selects one use channel in consideration with avoidance of the interference to/from nearby operating TVWS communication systems. In the field experiment in London, one of available channels with an permitted maximum power of EIRP +36 dBm is simply selected, since no other secondary system accesses the RLSS. After selecting the use channel, the AP starts to transmit beacons and the STA receives and replies them, then the TVWS communication is started.

B. Field Experiment in London Urban Area

In the field experiment in London, AP and STA were placed in Denmark Hill Campus and Guy's Campus of the KCL (King's College London), respectively, as shown in Fig. 8. A long-haul TVWS communication was performed with a line-on-site distance of about 3.7 km between the campuses. As aforementioned, output power at the antenna port is set to +27 dBm and 7.6 dBi directional antennas are connected to both devices. Therefore, transmission power of both devices is set to about EIRP +34.6 dBm with a 1.4 dB margin for the regulation. Throughput measurement was performed by using iperf with a signal bandwidth of 5 MHz, a QPSK modulation and a coding rate of 1/2. As a result, a UDP throughput of about 2.2 Mbit/s was obtained and it was confirmed that IEEE 802.11af-based communication system has the potential as a long-haul backbone network in a metropolitan environment.

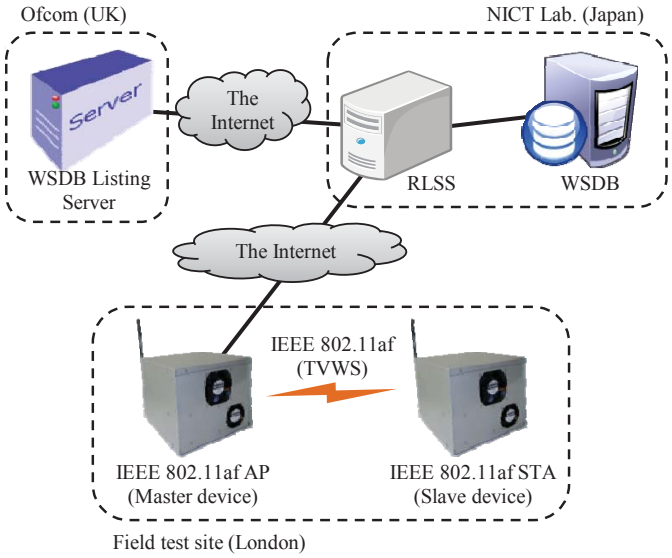

Figure 7. IEEE 802.11af-based communication systems for U.K. TVWS pilot program.

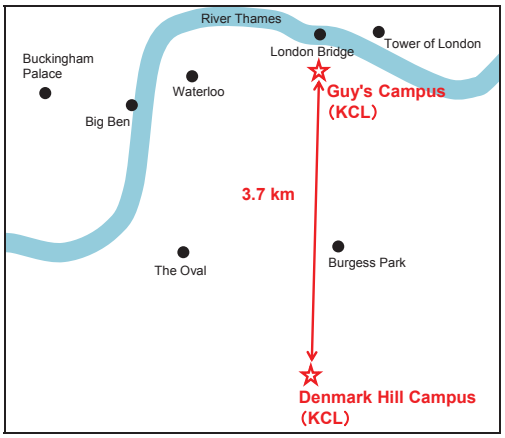

Figure 8. Location of field experiment in London urban area.

VI. CONCLUSION

In this study, the TVWS pilot program and required performance for secondary use of TVWS in the U.K. are summarized. Also, overview of the IEEE 802.11af-based prototyped device enabling a high output power of +30 dBm and its RF characteristics are presented. The prototyped WS devices comply with the ETSI draft specifications and are licensed by the Ofcom. In addition, field experiment was performed in London urban area by participating in the pilot program operated by the Ofcom.

As a result of the field experiment, a UDP throughput of about 2.2 Mbit/s with a signal bandwidth of 5 MHz was obtained with a 3.7 km line-on-site distance. Although the result of the throughput is not sufficient at present, this result indicates the potential as the long-haul backbone network based on the TVWS communication system even in the urban area where many high power TV broadcasters exist and interfere with the secondary system. For further improvement of the throughput, it is required to improve the blocking characteristics against strong interference from TV broadcasters. For the future work, these improvements will be carried out, to obtain the stability for the long-haul wireless communication in the TVWS even in the urban area.

ACKNOWLEDGMENT

Thanks for the King's College London for supporting the TVWS field experiment in the Ofcom TVWS pilot program.

***Abstract*—*Worldwide, the number of people having a chronic disease is increasing. Managing chronic diseases is time consuming and expensive. A need for new ways to deliver healthcare to patients with chronic diseases is urgent. Telemedicine and medical devices combined may offer several opportunities as alternative ways for healthcare to be delivered. An example of a device addressed to people with chronic disease is the device from the large-scale project "eWALL for Active Long Living", which has been tested using Participatory Heuristic Evaluation. The main results of the study showed a difference when comparing the most used heuristics given by the usability experts and the work domain professionals. When it comes to the distribution between the use of the severity grades between the usability experts and the work domain professionals, there seems to be an agreement between the two groups. For both groups the higher severity grade number 3 and 4 were more used than the lower severity grade 1 and 2. This Participatory Heuristic Evaluation of the eWALL interface application is the first iteration of the development process towards the final eWALL product. Future work includes the conduction of a second iteration, and perhaps third iteration, of Participatory Heuristic Evaluation on the eWALL interface application in order to optimize the usability of the final system.*

Keywords: telemedicine; eWALL; Participatory Heuristic Evaluation; chronic disease

I. INTRODUCTION

In the future, the correlation between a growing population of elderly people and people having two or three chronic diseases will lead to a massive organizational, economical, and professional challenge for the healthcare sector. Worldwide, the number of people having a chronic disease is increasing. In Denmark the chronic diseases such as: Chronic Obstructive Pulmonary Disease (COPD) and Mild Dementia (MD) affects more than thousands of people on a daily basis [1,2]. COPD is a lung illness characterized by a permanent blockage of airflow from the lungs [2]. The prevalence of COPD among people who have passed 35 year is approximately 14% [3]. MD is the mild form of dementia, which is the fifth frequent cause of death in Denmark [4].

Currently, the treatment of the chronic diseases is time consuming and expensive [5]. A need for new ways to deliver healthcare to patients with chronic diseases is urgent [6].

A new way of delivering healthcare service to patients with chronic diseases is to integrate telemedicine and medical devices into the standard ways that healthcare are currently delivered [6,7]. Medical devices cover a wide range of products, including wheelchairs, glasses, pacemakers, dental crowns and hip implants' [8]. The two terms, "telemedicine" and "medical devices", combined may offer several opportunities as alternative ways for healthcare to be delivered.

An example of a medical device, which is addressed to people with COPD, MD, and age related impairments, is the device from the large-scale project "eWALL for Active Long Living" [9]. The device can be used to monitor health of older adults, giving them easy access to doctors, and sensing daily activities with the aim of informing relatives in case of emergency. For the eWALL device, the overall technical and user requirements are: 1) unobtrusiveness in monitoring functions and 2) seamless interaction with primary and secondary end users (patients, healthcare professionals, and relatives).

Until now, the eWALL device has been tested using several evaluation methods, some of which are designed to provide feedback on the user-friendliness of the technology. The device is currently in the design and development phase, which means that there is still a need of removing usability issues from the system. One of the evaluation methods, which have been performed on the device with the objective to remove usability issues, is the so-called Participatory Heuristic Evaluation. In Participatory Heuristic Evaluation experts in usability perform an inspection as in a traditional heuristic evaluation followed by evaluation by work domain professionals [10]. The purpose of extending heuristic evaluation with work-domain professionals is to supplement the more theoretical knowledge of the traditional inspectors with the very specific knowledge from work-domain professionals. The Participatory Heuristic Evaluation reported in the present paper was performed as a part of the first iteration of the eWALL interface application.

The aim of the present study is to report the results and benefits of conducting a Participatory Heuristic Evaluation on the eWALL device. This paper is further organized as follows: Section II describes the materials and methods employed in eWALL and the overall layout of the interface. Section III presents the results of performing the Participatory Heuristic Evaluation. Section IV and V discuss and concludes the paper.

II. MATERIALS AND METHODS

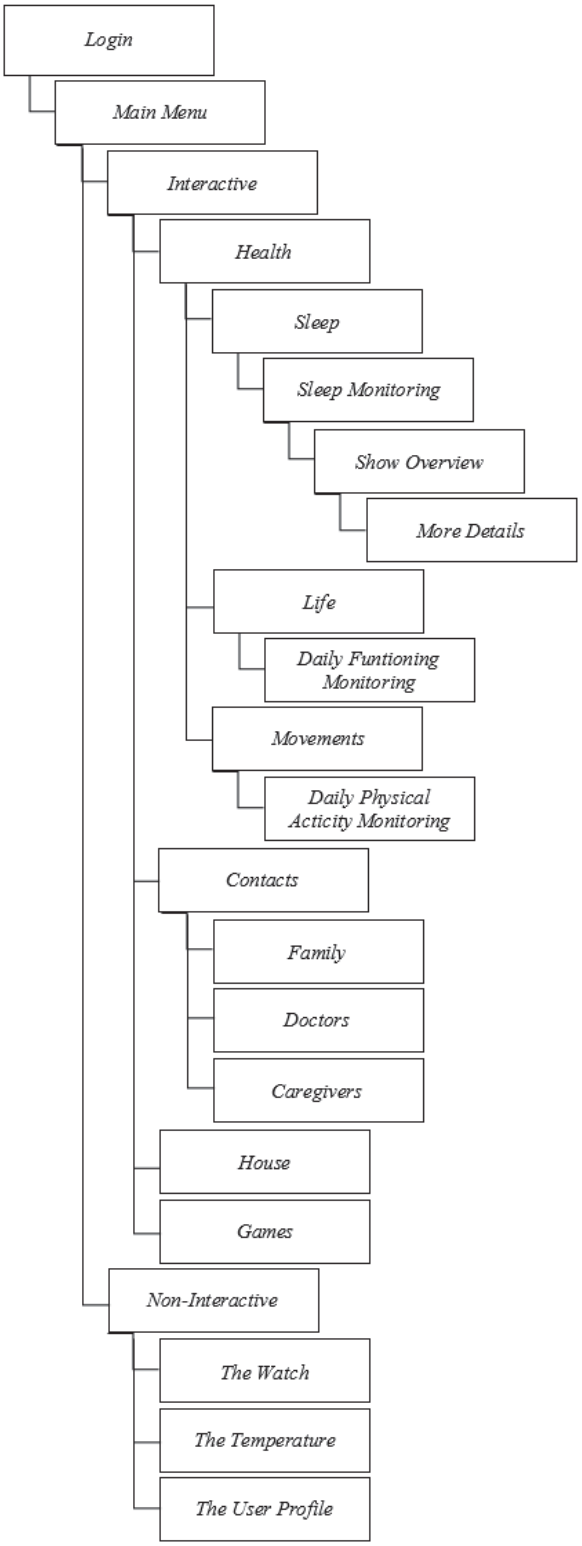

Fig. 1. *Architecture of the functionalities and features in the eWALL device*

A. The eWALL device

The eWALL interface application is an element of the final device, which is a prefabricated wall incorporating various functionalities and features for people with COPD, mild dementia, and age related impairment [9].

Fig. 1 visualizes the architecture of the functionalities and features which are integrated in the eWALL device. The figure shows that after logging in, the users have *interactive* and *non-interactive* services. The interactive services are categorized into the applications: Health, Contacts, House, and Games. Several of the applications have subgroups such as *Health* where it is possible to monitor *Sleep*, *Daily Functioning Monitoring*, and *Daily Physical Activity Monitoring*. The Non-Interactive services are *The Watch*, *The Temperature*, and *The User Profile*.

Overall, the functionalities and features of the eWALL system can be divided in three groups, namely the following: 1) Risk management; 2) eHealth; 3) Lifestyle management.

To get access to the functionalities and features in the eWALL interface application, the users have to enter a username and a password as seen in Fig. 2.

Fig. 2. *A screenshot of the front page where the users enter their username and password*

Next to the line where the users enter their username, there is a dropdown menu making it possible for the user to choose their native language as seen in Fig. 3.

Fig. 3. *A screenshot of the dropdown menu where the users choose their native language*

The non-interactive widgets include a digital watch and a weather application, which informs the users about 1) the

location, 2) the temperature of the day, 3) the cloud situation, 4) the pressure and 5) the wind speed. To make sure that the users understand everything, the information is both written and given by pictographs.

B. Participatory Heuristic Evaluation

As described in Section I, Participatory Heuristic Evaluation is a participatory inspection technique, which serves as an extension to the traditional heuristic evaluation defined by usability-expert Jakob Nielsen [11]. In the Participatory Heuristic Evaluation, five experts in usability were asked to identify and comment usability problems in the eWALL interface application. Furthermore, two work domain professionals were invited to contribute with their perspectives on the interface of the eWALL device.

a) Usability experts

To perform the Participatory Heuristic Evaluations five usability experts were recruited. All the usability experts had a MSc.in Biomedical Engineering. Three of the experts were PhD fellows and two experts were Associated Professors. The usability experts were all working at the Department of Health Science and Technology at Aalborg University. Three of them had prior experience in performing the Participatory Heuristic Evaluations. The remaining two usability experts were novices in performing a Participatory Heuristic Evaluation. All were familiar with traditional Heuristic Evaluation.

b) Work domain professionals

Two nurses were invited to participate as work domain professionals in the Participatory Heuristic Evaluations. Besides their profession as nurses, the work-domain professionals also had a MSc. in Clinical Science and Technology and were PhD fellows. The work-domain professionals were recruited from The Department of Health Science and Technology at Aalborg University. Both of the work domain professionals had experience with conducting Participatory Heuristic Evaluation.

c) Severity rating scale and 15 heuristics

The work-domain professionals and usability experts categorized and reported each usability issue using the 15 heuristics defined by Muller et al. [10]. In the following enumeration, the 15 heuristics are listed: 1) *System Status*, 2) *Task Sequencing*, 3) *Emergency Exits* 4) *Flexibility and Efficiency of Use*, 5) *Match Between Systems and the Real World,* 6) *Consistency and Standards,* 7) *Recognition rather than Recall,* 8) *Aesthetic and Minimalist Design,* 9) *Help and Documentation,* 10) *Help Users Recognize, Diagnose, and Recover from Errors,* 11) *Error Prevention,* 12) *Skills,* 13) *Pleasurable and Respectful Interaction with the User,* 14) *Quality Work,* 15) *Privacy.*

Every time a usability issue was identified, the usability experts and work domain professionals were requested to grade the usability problem using the following four level severity rating scale: 1) *Cosmetic problem only*, 2) *minor usability problem*, 3) *major usability problem*, and 4) *usability catastrophe*. By grading the usability problems, it was possible to collect information about how severe the usability problems of the eWALL interface device were.

The usability problems identified and the related severity grade were entered and categorized into columns in a Microsoft Excel worksheet. Subsequently, descriptive statistical visualizations were generated.

III. RESULTS

Fig. 4 shows the number of times each heuristic is used in total for the five experts, in total for the two work domain professionals, and in total for the usability experts and work domain professionals altogether. Heuristic no. 8, *Aesthetic and Minimalist Design* is the most used heuristic among the usability experts. The second most used heuristic is no. 6, *Consistency and Standards*, and the third most used heuristic is no. 5, *Match between the System and the Real World*. In comparison, the work-domain professionals use heuristic no. 6, *Consistency and Standards*, the most, heuristic no. 5, *Match Between the System and the Real World*, the second most and heuristic no. 13, *Pleasure and Respectful Interaction with the User*, the third most.

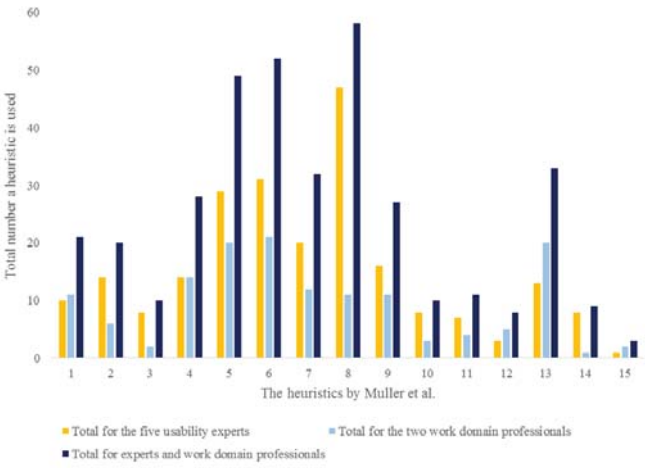

Fig. 4. *Number of times each heuristic is used in total for the five experts, in total for the two work-domain professionals, and in total for the usability experts combined and work-domain professionals altogether*

The diagram in Fig. 5 visualizes the total number of times each usability expert and work-domain professional has referred to a heuristic. Among the usability experts, the lowest total number of times a usability expert has referred to is 35 and the highest is 55. The difference between the lowest and the highest is 20 references. The work-domain professional no. 1 had the highest total use of heuristics, 91, and usability expert no. 2 had the lowest total use of heuristics, 52. The difference between the lowest and the highest is 39.

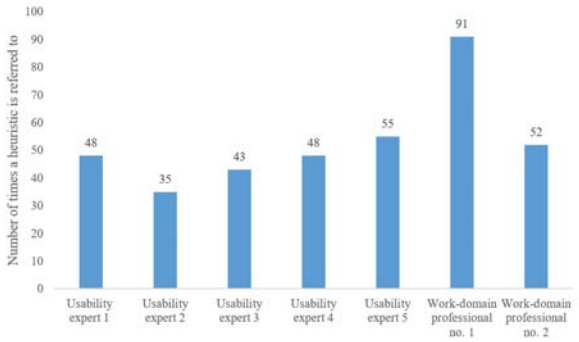

Fig. 5. *Number of times each usability expert and work-domain professional has referred to a heuristic*

Fig. 6 shows the total use of heuristics for each usability expert visualized in percent. Expert no. 2 represents the lowest, 15% of the total, and expert no. 5 represents the highest, 24% of the total.

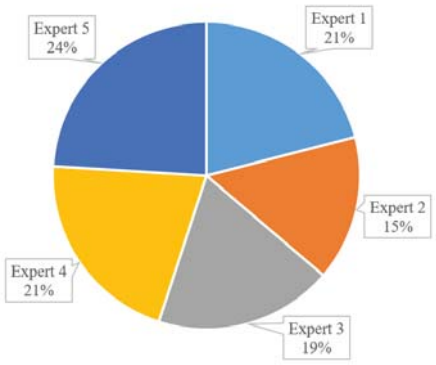

Fig. 6. *Total use of heuristics for each usability expert visualized in percent*

Figure 7 visualizes each work-domain professionals' total use of heuristics during the Participatory Heuristic Evaluation. The work-doman professional no. 1 represents 64% of the total use of heuristics. In comparison, work-domain professional no. 2 represents 36% of the total.

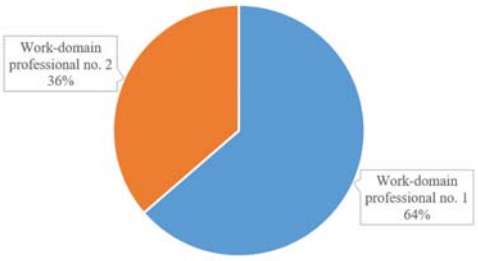

Fig. 7. *Total use of heuristics for each work-domain professional visualized in percent*

Fig. 7 shows the number of times each severity grade was used by the usability experts and by the work domain professionals.

For both groups, severity grade no. 3, *major usability problem*, was the most used and severity grade 4, *usability catastrophe*, was the second most used.

Fig. 8. *Number of times each severity grade was used by the usability experts and by the work domain professionals*

DISCUSSION

The aim of the present study was to report the results and benefits of conducting a Participatory Heuristic Evaluation on the eWALL interface application. In the Participatory Heuristic Evaluation, five usability experts and two work domain professionals were invited to participate. The five usability experts had theoretical knowledge in the field of usability and interface applications and the two work domain professionals had more practical knowledge in the domain area. The two groups of experts represented quite different perspectives when doing the Participatory Heuristic Evaluation.

The main results of the study showed a difference when comparing the most used heuristic given by the usability experts and the work-domain professionals. This might be seen as an illustration of how the work-domain professionals probably have a very strong focus on a respectful interaction with the user, where the usability experts are having a more theoretical approach, which is focused more on aesthetics and a minimalistic design.

When it comes to the distribution between the use of the severity grades between the usability experts and the work domain professionals, there seems to be an agreement between the two groups that the eWALL interface applications contains severe usability problems. 66 times did the usability experts refer to the severity grade 3 *major usability problem* and 68 times did the work-domain professionals refer to the same grade (see Fig. 8). For both groups the severity grade number 3 and 4 were more used than the lower severity grade 1 and 2.

Developing a system requires several phases of testing and rounds of iterations [12,13]. This study is the first iteration in the development phase of the eWALL interface application. The results from the study indicate that there is a need for more iterations. According to the usability expert Jakob Nielsen it is mandatory to evaluate a system during the development phase because potential usability irritations can be more easily removed and thereby help to keep the users interested in using the system [14].

In the present study, the Participatory Heuristic Evaluation was performed on the eWALL interface application. The

strength of using the extended technique is that the system will be evaluated from more perspectives – both more theoretical and more practical perspectives. Another strength of the study is that by using heuristics, it is possible to collect quantified data, because the usability experts categorize each problem into a heuristic and a severity rate. Finally, it is a strength that it is relatively straightforward to perform a Participatory Heuristic Evaluation session – it is the usability experts and work domain professionals who articulate the problems. A potential weakness of the Participatory Heuristic Evaluation is that for sure not all usability issues will be identified. A weakness of the paper is that only two work domain professionals participated. It had been more likely if five work domain professionals had participated in order to have an equal number of usability experts and work domain professionals.

IV. CONCLUSION

Performing a Participatory Heuristic Evaluation on the eWALL interface application has given very usable and relevant results. The usability experts have provided a more theoretical perspective on the eWALL interface application, and the work domain professionals have provided a more practical perspective on what is necessary to improve in the eWALL interface application.

Conducting this Participatory Heuristic Evaluation on the eWALL interface application is the first iteration of the development process towards the final eWALL product. The results indicate a second iteration of the eWALL system.

Future work includes the conduction of a second iteration, and perhaps a third iteration of Participatory Heuristic Evaluation on the eWALL interface application in order to optimize the usability of the final system.

ACKNOWLEDGMENT

The authors would like to thank usability experts and work-domain experts who participated in the Participatory Heuristic Evaluation. The work was funded by the eWALL project, which receives funding from EU's 7th Framework Programme for Research, Technological Development and Demonstration; grant no. 610658.

Coexistence of Systems with Different Multicarrier Waveforms in LSA Communications

Mirza Golam Kibria, Gabriel Porto Villardi, Kentaro Ishizu and Fumihide Kojima
Wireless Network Research Institute, National Institute of Information and Communications Technology, Japan
E-mail: {mirza.kibria, gpvillardi, ishidu, f-kojima} @nict.go.jp

***Abstract*—We study the coexistence of different multicarrier waveforms such as orthogonal frequency division multiplexing (OFDM), filter-bank multicarrier (FBMC) and universal-filtered multicarrier (UFMC) waveforms in licensed shared access (LSA) for next-generation communication systems. The fundamental changes required in the existing physical layer using OFDM towards a hybrid physical layer (either OFDM-FBMC or OFDM-UFMC) ensuring backward compatibility are discussed. We also perform mutual interference analysis for the coexisting asynchronous systems sharing the LSA frequency band. Because of the non-orthogonality between their respective transmit signals, power is spilled from a system to the other causing interference. In consideration of analyzing this interaction, power spectral densities of the multicarrier waveforms are exploited. We quantify the amount of percentage power-loss experienced by the interfering systems for not fully exploiting their available power budgets. The simulation results reveal that the interfering system with FBMC suffers the least percentage power-power loss due to its very low side-lobes while conventional OFDM-based system suffers the most. The UFMC-based system exhibits intermediary performance with respect to achieved throughput and power-loss when compared with OFDM and FBMC-based systems.**

***Index Terms*—Licensed shared access, Coexistence, Multicarrier waveforms, etc.**

I. Introduction

Radio spectrum is an extremely valuable resource. The exponential increase in demand for technologies like Wi-Fi or smart electricity grids means we must use this finite resource efficiently. But meeting that growing demand for wireless connectivity is harder in the absence of vacant spectrum. In traditional exclusive licensing systems, many spectrum bands are spatially and temporally underutilized. Due to the scarcity of the spectrum resources and to support the enormous wireless traffic explosion in future, it is important to make full use of the existing radio resources. Spectrum sharing presents a supplementary approach to conventional license-exempt and exclusive licensing schemes. Even though many applications still depend on exclusive access to spectrum, spectrum sharing is increasingly recognized as the breeding ground for wireless innovation that stimulates the development and deployment of more resilient wireless technologies. Licensed shared access (LSA) [1] facilitates dynamic and effective use of available frequency spectrum in next-generation communication networks, and it is likely to become undeniably essential to support the anticipated massive wireless traffic outburst.

The flagship of multicarrier techniques is orthogonal frequency division multiplexing (OFDM). OFDM is currently the transport mechanism base for LTE, LTE-Advanced and WiMAX systems. Although OFDM exhibits several remarkable attributes, it has two inherent shortcomings: susceptiveness to carrier frequency offset (CFO) and a large signal peak-to-average power ratio. With accurate inter-system synchronization, there is no mutual interference between the systems, when different systems use different sets of subcarriers. But if there is synchronization mismatch, the mutual interference will be very high because of the high spectral side-lobes of OFDM signals, which results in low spectral efficiency. At present, the networks of different systems are mostly not synchronized to each other. Furthermore, the OFDM access (OFDMA) based schemes require all systems to use an identical signal frame structure with alignment in time. However, 5G systems need to accommodate a large variety of devices and use cases, which require flexible frame structures. Therefore, the OFDM-based schemes cannot fulfill such 5G requirements.

Finding an appropriate substitute for OFDM is an important issue in 5G research. One basic requirement of 5G is a flexible air interface where the multicarrier attribute like subcarrier spacing is optimizable depending on specific system requirements [2]. In next-generation systems, devices could communicate based on both open-loop and closed-loop protocols that require parameter optimization, which is probable to be translated into interference. OFDM lacks the ability to address these issues. One of the contender waveforms is filter-bank multicarrier (FBMC) [3]. However, For short burst transmissions, FBMC lacks efficiency due to high time domain overheads [4]. These shortcomings exhibited by OFDM and FBMC have led some companies and organizations to transfer their focus to finding a more suitable waveform.

A new multicarrier waveform called universal-filtered multicarrier (UFMC) [3], also referred to as UF-OFDM, has attracted a great deal of attention due to its better efficiency than OFDM. UFMC can be seen as a generalization of OFDM and FBMC. The ultimate goal of employing UFMC is to combine the advantages of OFDM and FBMC while avoiding their main drawbacks. By filtering groups of adjacent subcarriers, the side-lobe levels (compare with OFDM) and the prototype filter length (compare with FBMC) can be simultaneously significantly reduced and becomes adjustable depending on types of applications. UFMC is also found to be a well-suited modulation technique for systems including option for short burst transmissions [3].

In this paper, we study the coexistence of the above men-

tioned waveforms in LSA scenario. The fundamental changes required in the existing physical layer using OFDM towards a hybrid physical layer ensuring backward compatibility are discussed. We also perform mutual interference analysis for the coexisting systems sharing the LSA frequency band.

II. System Model

We consider a co-primary LSA communication system with L systems. The LSA spectrum is licensed to multiple systems without defining distinct edge between the bands of different systems. The sharing of the spectrum is accomplished through a common entity called spectrum manager in a coordinated way. The systems have the flexibleness in employing different air-interfaces that support scalable bandwidth and discrete Fourier transnform. A common subcarrier grid of N_c subcarriers is formed as in [5]. Note that the LSA spectrum can be both contiguous and non-contiguous.

A uniform common subcarrier grid, $\mathcal{U}_{\text{grid}}$ is assumed, i.e., even if the available LSA spectrum is non-contiguous, $\mathcal{U}_{\text{grid}}$ covers the available full LSA spectrum. The spectrum assignment among the systems can be performed in two different ways, (i) subcarrier based allocations (ii) fragment based (contiguous band) allocation. Let $\{\mathcal{U}_1, \cdots, \mathcal{U}_L\}$ be the sets of indices of the subcarriers assigned to LSA compliant systems and $\mathcal{U}_{\text{grid}} = \mathcal{U}_1 \cup \mathcal{U}_2 \cup \cdots \cup \mathcal{U}_L$. In case of fragment based allocation, the subcarriers in $\mathcal{U}_l$ are adjacent in $\mathcal{U}_{\text{grid}}$. In LSA communication, the overall spectrum allocation process is achieved in two stages. In the first stage, the spectrum manager assigns sets of subcarriers or fragments to the systems and in the second stage, the systems perform resources (frequency and power) allocation optimization independently. With perfect synchronization or adequate guard bands between the fragments, each system can transmit data to its own serving users independently without causing interference to the users served by other systems.

III. Coexistence of OFDM and FBMC/UFMC Waveforms in Hybrid PHY Layer

In our waveform coexistence analysis, OFDM is fixed as the waveform of the legacy system and we discuss the fundamental changes required in the existing physical (PHY) mode using only OFDM waveform towards a hybrid PHY mode (either OFDM-FBMC or OFDM-UFMC) ensuring backward compatibility with legacy systems. Note that in 3GPP standardization there is a tendency to reduce options as far as possible for the sake of testing and implementing. We view the hybrid PHY mode as transitory that eases the migration towards the use of either FBMC or UFMC in the future. Therefore, we envisage the use of either FBMC or UFMC in a network such that the stations able to perform FBMC or UFMC should also be able to perform OFDM, at least in the transition period. Note that the stations of the legacy OFDM system do not have the capability to demodulate FBMC/UFMC signals.

Let us consider a hypothetical intra-system coexistence scenario in the transition period where the BS and some of its associated mobile stations are capable of performing FBMC/UFMC. The association of the FBMC/UFMC stations in the system is achieved by following the normal OFDM procedures such as initial ranging [6]. During the ranging process, the FBMC/UFMC stations notify the BS regarding their capabilities of performing FBMC/UFMC. The BS allocates a certain zones of the frames for FBMC/UFMC transmissions, preferable at the end of the frames, to minimize the disturbance as the stations of the legacy system cannot demodulate FBMC/UFMC signals. Both FBMC and UFMC systems are likely to coexist with OFDM systems. Since FBMC and UFMC are the evolutions of OFDM, some compatibility are expected. All these modulation techniques are based on fast Fourier transform (FFT), and they have a common core. In particular, the initialization phase can be regular to both of the hybrid PHY modes. However, presence of CP in OFDM makes the streaming of the signals different.

A. Hybrid PHY mode: OFDM-FBMC

Compatibility begins at the specifications and system parameters level. The sampling frequency is the same and the subcarrier spacing of FBMC is equal to the subcarrier spacing of OFDM or it is a sub-multiple, so that the FFT is the same, or a subset of the FFT is the same. The difference is that the IFFT is running at double speed for FBMC due to offset-quadrature amplitude modulation (OQAM). In Fig. 1 and Fig. 2, we illustrate the adjustments required to the legacy system's transmitter to implement a hybrid PHY mode: OFDM-FBMC. Here white blocks are common to both modes while blue blocks are FBMC specific, orange blocks OFDM specific. The gray blocks indicate structures needed in both modes, however, differing in implementation.

Burst generation includes the bit source, forward error coding and symbol mapping. In the multiuser case several bursts are generated. The frame generator builds the frames to be transmitted including the user bursts and the preamble. These two blocks are common between OFDM and FBMC mode. The first adjustment to the legacy OFDM transmitter is performed by adding OQAM block that transforms the QAM to OQAM symbols. This unit is specific to FBMC mode, thus gets bypassed when OFDM mode is active. Pilots are needed in both modes for channel estimation and equalization at the receiver. However, preprocessing of pilot symbols are different. In OFDM mode, pilots are binary phase shift keying (BPSK) symbols. However, in FBMC mode, pilot processing is more complicated compared to OFDM mode. As channel coefficients typically are complex (in baseband notation) the interference caused by adjacent data symbols would disturb channel estimation. To cancel this interference, auxiliary pilot method is used in PHYDYAS. The signal generation in OFDM mode is triggered by inverse FFT (IFFT) and the addition of the CP, while in FBMC mode, the synthesis filter-bank does the job. This is the most significant adjustment needs to be performed to realize hybrid OFDM-FBMC PHY mode.

The signal processing in the hybrid receiver is a bit more complicated, but can be implemented using the same principles followed in transmitter implementation. A large part of the

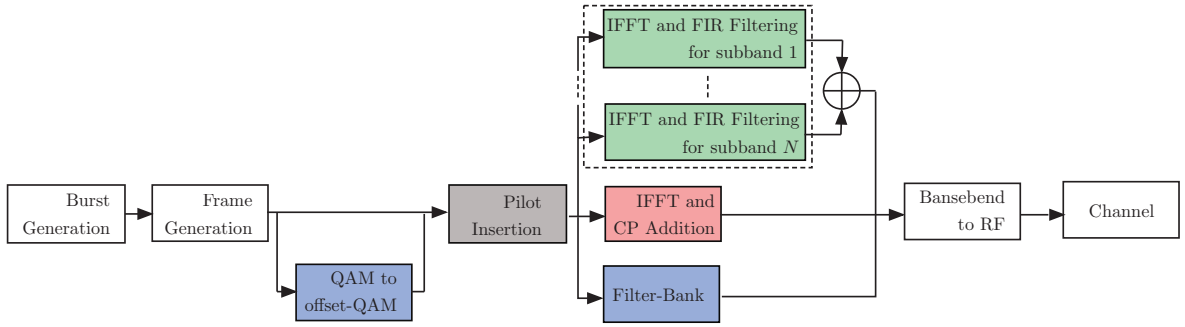

Fig. 1. Operation-flow in hybrid PHY mode transmitter including OFDM-FBMC and OFDM-UFMC modes.

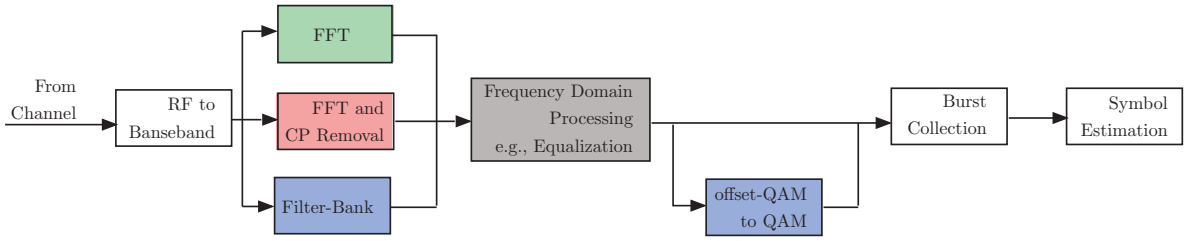

Fig. 2. Operation-flow in hybrid PHY mode receiver including OFDM-FBMC and OFDM-UFMC modes.

transmitter functions have their counterpart in the receiver. Therefore, the hybrid transmitter design can be reused in the design of a hybrid receiver. The received signal gets transformed employing an FFT after the removal of the CP, if OFDM mode is active. When the FBMC mode is active, the analysis filter-bank performs the transformation. Channel estimation, synchronization and equalization are required in both modes, differing in their implementation. Conversion from OQAM to QAM symbols is needed only in FBMC mode. Like in transmitter, this block gets bypassed if OFDM mode is active. Operations relating to burst collection and symbol estimation/detection are common to both modes.

B. Hybrid PHY mode: OFDM-UFMC

Note that UFMC is subband-wise filtered and UFMC with filter length 1 is identical to non-CP OFDM. Due to this close relationship, reusing existing OFDM transceiver parts is easy. At the transmitter, all processing leading to complex frequency-domain modulation symbols, e.g. QAM, at the multicarrier modulator input is identical. In Fig. 1 and Fig. 2, we illustrate the adjustments required to the legacy system's transmitter to implement a hybrid PHY mode: OFDM-UFMC. Here white blocks are common to both modes while green and orange blocks are UFMC and OFDM specific, respectively. The gray blocks indicate structures needed in both modes, however, differing in implementation. Since UFMC also employs QAM, the burst generation, frame generation and pilot insertion blocks are common to both modes. Triggering of signal generation for UFMC mode is a bit different from the OFDM mode. In UFMC mode, for a group of consecutive subcarriers, the IFFT operation is done deriving the corresponding set of IFFT vectors and then filtering by an FIR-filter.

Regarding the signal processing in the hybrid receiver, when UFMC mode is active, after 2-N FFT, picking each second output and dividing by the frequency response of the filter, yields the same frequency domain scalar per-subcarrier processing as in OFDM. As a result, all existing OFDM channel estimation algorithms can be directly reused by UFMC. In general, just the functionality of multicarrier modulation/demodulation has to be replaced while the rest remains the same.

IV. Mutual Interference Analysis for Coexistence of Systems with Different Multicarrier Waveforms in LSA

A. Interference Analysis of OFDM Signal

Assuming an ideal Nyquist pulse, the power density spectrum of any subcarrier in OFDM signal is written as [7]

$$\Psi_{\mathrm{OFDM}}(f) = PT_s\left(\frac{\sin(\pi f T_s)}{\pi f T_s}\right)^2, \tag{1}$$

where P amounts for transmit power on the subcarrier and T_s stands for symbol duration. Therefore, the PDS of any OFDM RB can be expressed as

$$\Phi_{\mathrm{OFDM}}(f) = \sum_{n=0}^{N_{\mathrm{RB}}-1} \delta(f - n\Delta f) P_n T_s \left(\frac{\sin(\pi f T_s)}{\pi f T_s}\right)^2, \tag{2}$$

Here N_{RB} is the number of subcarriers in a RB and δ is Dirac delta function. P_n is the amount of power allocated to the nth subcarrier. This is a sum of shifted, weighted Sinc functions.

B. Interference Analysis of FBMC Signal

In an FBMC system, we define the prototype coefficients as $h[l]$, with $l = 0, \cdots, L-1$, where $L = KM + 1$ and K is the length of each polyphase components. We define the variable $\mathcal{L} = KM/2$ and assume that the prototype has even symmetry

around the $\mathcal{L}$-th coefficient, this means that $h[l] = h[KM - l]$. The PDS of any RB in FBMC signal is given by

$$\Phi_{\text{FBMC}}(f) = \sum_{n=0}^{N_{\text{RB}}-1} \delta(f - n\Delta f)\, \overbrace{P_n \left(\sum_{k=-K+1}^{K-1} H_k \frac{\sin(\pi(f - \frac{k}{NK})NK)}{\pi(f - \frac{k}{NK})NK} \right)^2}^{\Psi_{\text{FBMC}}(f)},$$

where H_k are the polyphase components defined in [4] with $H_0 = 1$ and $H_k = H_{-k}$. $\Psi_{\text{FBMC}}(f)$ is the PDS of nth subcarrier in the RB.

C. Interference Analysis of UFMC Signal

UFMC employs Dolph-Chebyshev [8] filter as an ad hoc choice. One notable property of Chebyshev window is that side-lobes attenuation remains same at all frequencies. In UFMC, the original OFDM spectrum is filtered by Chebyshev filter. Thus, the well-known Sinc-spectrum of OFDM also plays a role, which results in the decaying side-lobes in UFMC. The filter coefficients in time-domain are defined as

$$\Psi^{(n)}_{\text{UFMC}} = \begin{cases} \left\{ \frac{1}{N} + \frac{(10^{-\alpha/20})}{N} 2 \sum_{m=1}^{M} C_{2M} \left[\kappa_0 \cos\left(\frac{\pi m}{N}\right) \right] \cos\left(\frac{2\pi mn}{N}\right) \right\}, & \text{for } |n| \le M \\ 0, & \text{for } |n| > M \end{cases}$$

where $N = 2M + 1$ is the UFMC filter length, κ_0 is a filter parameter and C_n is the nth order Chebyshev polynomial. α defines the side-lobe attenuation in dB.

Since UFMC is subband-wise filtered, to generate the PDS of any individual subcarrier of UFMC signal, we send zeros at other subcarrier positions of the RB and the UFMC filter response is shifted to the centre frequency of the RB by multiplying the l the coefficient of the filter with $e^{i2\pi(l-1)f_c \frac{1}{N_{\text{FFT}}}}$. The amplitude of any subcarrier of UFMC signal in time domain is then obtained by performing convolution between OFDM subcarrier and the centre frequency shifted UFMC filter coefficients. Let the PDS of a single subcarrier in UFMC signal is represented by $\Psi_{\text{UFMC}}(f)$. Then the The PDS of the UFMC RB is given by

$$\Phi_{\text{UFMC}}(f) = \sum_{n=0}^{N_{\text{RB}}-1} \delta(f - n\Delta f)(\Psi_{\text{UFMC}}(f))^2. \quad (3)$$

Since UFMC is RB-wise filtered, outside of the pass-band (RB width) it has a stronger side-lobe decay than OFDM. The interference from the interfering system to the other coexisting systems is defined as

$$\text{I}_n(\text{d}_n) = \int_{(\text{d}_n - 1/2)\Delta f}^{(\text{d}_n - 1/2)\Delta f + B_{\text{sys}}} \Psi_{\text{W-Type}}(f) df. \quad (4)$$

Here, d_n is the spectral distance between the nth subcarrier of the interfering system and the adjacent system. The total interference introduced to any system is a result of accumulation of interferences from all the RBs available for interfering system's transmission. In Fig. 3, power spectral densities of systems with different multicarrier waveforms are compared. It clearly shows that FBMC exhibits the best performance in terms of out-of-band emission because of very low side-lobes.

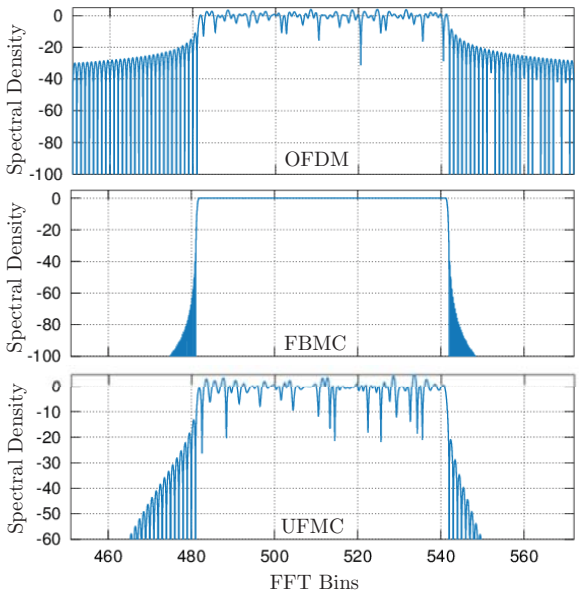

Fig. 3. Comparison of power spectral densities with 60 subcarriers.

V. Performance Analysis

Let us consider an LSA scenario with two coexisting systems operating in contiguous LSA band of 20 MHz bandwidth. We denote the systems as system-A and system-B. The effective bandwidth is taken as 18 MHz with 10% of the bandwidth assumed to be used for guardband with other nearby systems. Hence, the total number of subcarriers in the subcarrier grid is 1200, with subcarrier spacing of 15 kHz. Consequently, the number of RBs is 100, with 12 subcarriers per RB. The shared 18 MHz spectrum is partitioned into two halves, each for one coexisting system. The coexisting systems may employ different waveforms and obtain orthogonal sets of RBs for transmission. The transmit power budget for each system is taken to be P_{max}=43 dBm. Each system allocates the resources to its users independently. For simplicity, we consider that each system has one base station (BS) and supports 10 users. The interference-tolerant LSA coexisting systems have their own interference thresholds, e.g. $I_{\text{th,A}}$ for system-A and $I_{\text{th,B}}$ for system-B. For simplified performance analysis, we assume that both of the systems have equal threshold values, i.e. $I_{\text{th,A}} = I_{\text{th,B}} = I_{\text{th}}$. We vary the values of I_{th} from 10^{-6} w to 10^{-1} w. For UFMC, the filter length is 74 with $\alpha = 40$ dB.

The transmission capacity of the coexisting systems versus interference introduced to adjacent system is plotted for OFDM, FBMC and UFMC in Fig. 4. It is seen that the achievable throughput of the system can be improved by relaxing the interference threshold of the adjacent systems. OFDM-based system achieves the least downlink capacity compared to FBMC and UFMC based systems while UFMC-based system experiences intermediary performance between OFDM and FBMC-based systems. When the maximum amount of tolerable interference is very small, i.e., for non-robust systems, FBMC exhibits the best performance. Note that the achievable

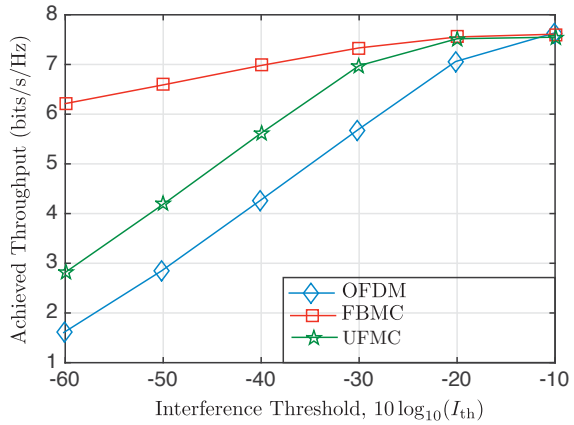

Fig. 4. Achieved throughput of system-A vs. interference threshold of system-B (or vice versa).

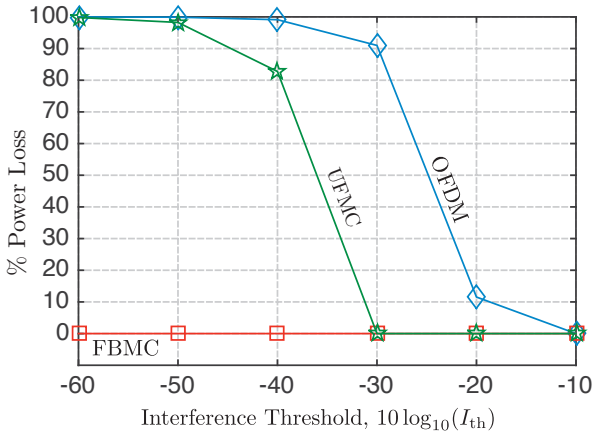

Fig. 5. Percentage power-loss of the coexisting systems. The loss is calculated as, %power-loss = $100 - P_{\text{used},I_{\text{th}}}/P_{\max} \times 100$, where $P_{\text{used},I_{\text{th}}}$ is the transmit power used by the the systems to satisfy the interference threshold I_{th}.

capacity for UFMC based system depends on the chosen value for desired sideband attenuation. Higher the value of sideband attenuation factor α, better the achievable downlink capacity. As the interference threshold values increase, therefore, for robust systems, the achievable capacity of FBMC and UFMC-based systems seem to merge depending on the chosen ripple factor and pre-specified interference thresholds. This result motivates the usage of FBMC when no accurate inter-system synchronization is available. Therefore, spectrum sharing are favored scenarios for FBMC, where either the spectrum usage policy is more stringent in terms of emission requirements (such as adjacent channel leakage ratio), or where the requirement is to be more coexistence-friendly to other systems.

In interference-tolerant coexisting systems, a practical way to manage the mutual interference between different systems is by regulating the transmit power in order to comply with the pre-specified interference threshold of different systems in LSA. As a result, the systems cannot fully exploit the maximum benefit out of their available power budget. This is clearly demonstrated in Fig. 5, where we show the *%power-loss* of the coexisting systems with different waveforms when the pre-specified interference threshold value is varied. It can be observed that OFDM-based system experiences the maximum *%power-loss*, whereas FBMC-based system does not suffer from *%power-loss* at all over the varying I_{th} values. On the other hand, UFMC based system suffers much lower *%power-loss* compared to the OFDM-based system. The characteristics of the power-loss curves depend on the spectrum usage policy whether it is more stringent in terms of some emission requirements. For example, when the spectrum usage policy is not so stringent ($I_{\text{th}} \in [-30 \; -20]$) dBw, UFMC-based system does not suffer from any *%power-loss* even with lower α. However, for non-robust systems, the *%power-loss* experienced by the UFMC based system increases.

VI. Conclusions

In this paper, we investigate the coexistence of different multicarrier waveforms in LSA communications. We discuss the fundamental changes required in the existing physical layer using OFDM waveform towards a hybrid physical layer (either OFDM-FBMC or OFDM-UFMC) ensuring backward compatibility with legacy systems. We have found that hybrid mode terminals can be designed with just a modest increase in complexity of the physical layer compared to a pure OFDM terminal. FBMC and UFMC systems are able to substitute OFDM maintaining a great amount of physical layer compatibility for the future communication networks. We also perform mutual interference analysis for the coexisting asynchronous systems sharing the LSA frequency band. Simulation results have revealed that the interfering system with FBMC suffers the least percentage power power loss due to its very small side-lobes while conventional OFDM-based system suffers the most. The UFMC-based system exhibits intermediary performance with respect to achieved throughput and power loss when compared with OFDM and FBMC-based systems.

***Abstract*—Energy Efficiency is a key performance index for the communication networks. And with the increasing diversity of wireless services, green communication for hybrid services with less consideration has become important and drawn more attention recently. In this paper, we proposed a novel mapped water falling allocation scheme (MWF) to achieve total energy consumption minimization in cellular network. Our scheme exploits the enormous property differences of the services to complete the resource allocation while satisfying the QoS requirements which are analyzed through queuing theory. The complicated resource allocation problem that cannot be resolved with analytic solutions is separated into two subproblems, time slot selection and rate allocation, which can be solved more simple respectively and we get a closed form solution for the second subproblem. Experimental simulation results verify that our scheme outperforms the two others on energy efficiency under any circumstances.**

I. Introduction

Along with the exponential growth of mobile data traffic over the last years, it is widely acknowledged that the energy consumption of wireless network has risen considerably with the evolution of ICT [1][2]. And there is an sharply growing gap between the energy demand and the battery capacity because of the rising device power consumption and slower battery development [3]. As the result, green communication is becoming more important and getting more attentions. At this time, large capacity and high spectrum efficiency are no longer the unique target we need to concern.

For single service, various researches have been made to utilize delay to reduce the energy consumption of the system while satisfying the QoS requirements [4]-[12]. Moreover, there are variety of mathematical methods applied to analyze energy problem, including game theory [5], queuing theory [6] and convex optimization [7]. With the development of wireless network and the emersion of new services, mobile terminals will transmit or receive hybrid services simultaneously sometimes. Unlike the single service case, hybrid services need to share all the transmission resource that is limited in a system.

To settle this problem, in the scenarios where fixed and variable rate services coexist, the authors in [8] proposed a scheme that dynamically regulate the transmission bandwidth allocated to the variable rate service when a terminal can access some different networks at the same time. Paper [9] takes the utility of service fairness into account on bandwidth distribution. In [10], a cross-layer cooperative delay-energy tradeoff (CCT) scheme is presented based on energy efficiency for mixed transmission in cellular network. But little attention has been paid to the feature of different services in these papers. Moreover some schemes that they proposed like DGA of CCT are relatively complicated, which is unpractical and unfeasible.

Since the above defects we refereed, we propose a novel mapped water falling scheme for hybrid services to achieve the optimal energy efficiency in cellular network. Unlike other papers, we consider the feature of service more precisely and utilize the queue theory to analyze the QoS requirements. It can be known that the resource allocation problem combining the application and the physical layer is NP-hard and we cannot get analytic solutions with closed form. In this paper, we separate the NP-hard problem into two subproblems that can be solved more easily respectively and we get a closed form solution for the rate allocation subproblem, ingeniously. Moreover our scheme that exploiting the enormous differences of service feature between hybrid services is more effective and practical compared with other traditional schemes.

The rest of the paper is organized as follows. In section II, we describe the system model for hybrid services in cellular network. And then section III studies our proposed mapped water falling allocation scheme in details. Section IV presents the simulation experiment and analyzes the results. Finally, we conclude the paper in section V.

II. System model

In order to facilitate our analysis and without lose the generality, we assume only one mobile user exchange information with the base station over a period of time. If there are multiple mobile terminals, they can be regard as a single virtual one by gathering all the services together.

As shown in Fig.1, there are M kinds of services between the mobile terminal and the base station which have different data characteristics and QoS requirements. In this paper, we only consider the downlink transmission and uplink can be obtained in the same way. The arrival rate, the average length of data packet and the delay demand of the M services are donated by λ_1, λ_2, λ_3, $\cdots$, λ_M;L_1, L_2, L_3, $\cdots$, L_M and D_1, D_2, D_3, $\cdots$, D_M (time slot) respectively. Moreover the

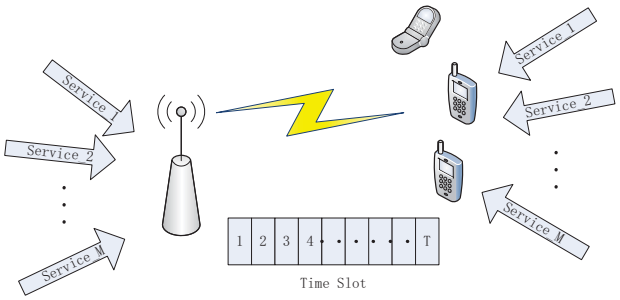

Fig. 1. Hybrid services transmission system in cellular network

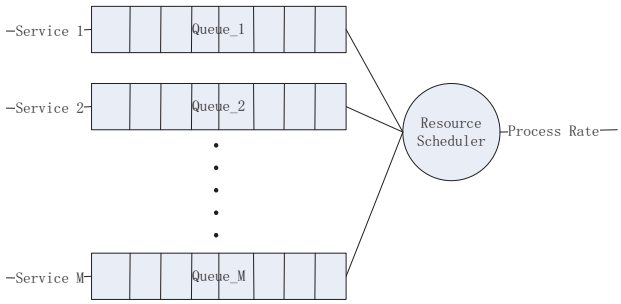

Fig. 2. The queuing model of hybrid services system (downlink)

data arrival process is a Poisson process with the parameter of arrival rate and the length of the packet obey Poisson distribution. Data packets that need to be transmitted are waiting in an infinite service queue. In other words, it can accommodate all the data packets without loss. And the resource scheduler decides when the packets will leave and the leaving rate.

It is assumed that the terminal and the base station both have full CSI and can perfectly predict the channel condition of the next T time slots. Considering the path loss and large scale fading, the channel coefficient between the two nodes can be denoted by h_t at time slot t. Furthermore, we consider a quasi-static fading channel for which the channel coefficient are constant within one slot but change independently form one slot to another. The additive white Gaussian noise is denoted by $\nu \sim \phi\ (0,\ \delta_t^2)$.

In a single time slot, the transmission power of the base station is fixed, indicating the data rate is fixed. But in different time slots, the base station can change its transmission power dynamically to achieve the rate adaption. We assume that the channel modulation and coding schemes can approach the Shannon capacity bound which can make the transmission power consumption minimum. Note that standard Shannon capacity is adopted in this paper, which represents channel capacity bound per unit bandwidth.

III. Mapped Water Falling Allocation Scheme

A. Problem Formulation

The resource for hybrid services in the system as we concern involves transmission time slots and power (rate). As we all acknowledged that service is invisible in physical layer, the rate assignment of each time slot isn't influenced by the fact that which service occupied this slot on earth. So for briefness and feasibility, the complicated resource allocation problem is divided into two subproblems as follows:

1: Select appropriate transmission time slots for each service.

2: Allocate suitable transmission rate at the time slots assigned to the service.

In this section, we first explore the QoS requirements of hybrid services. The queuing model of the system is illustrated in Fig.2. Data rate of service m at time slot t is denoted by r_m^t. Let $r_m^t = 0$ where the time slot is not selected. In each time slot, the departure of the data packets can be regarded as a non homogeneous Poisson process with the parameter of $\mu_m^t = \frac{r_m^t}{L_m}$, where μ_m^t is changing with the time slot.

A single service queue is a compound process containing a homogeneous Poisson arrival and heterogeneous Poisson departure. We propose a queue equivalent lemma to transform the heterogeneous Poisson process into a homogeneous one.

Lemma 1: In a single server queuing system where the arrival rate is fixed, the arrival and the departure process are both Poisson process. The average performance of the system is equivalent by using the two method below:

Method 1: The data packets leave with rate μ over a period time of $n \times T_{slot}$.

Method 2: The data packets leave with rate $\mu(t)$ which satisfies the following constraint:

$$n \times T_{slot} \times \mu = \int_0^{n \times T_{slot}} \mu(t)dt \tag{1}$$

The proof is so simple and apparent that we leave out it for the sake of limited space. According to lemma 1, the compound queuing process can be equivalent to a birth-death process with a fixed leaving rate $R_{mean,m}$. At this time, the queuing model is a standard $M/M/1$ model.

The paper mainly consider the average delay characteristic of service, which is statistical. In this way the QoS requirement can be expressed as:

$$Delay_m = \frac{1}{\frac{R_{mean,m}}{L_m} - \lambda_m} \leq D_m \times T_{slot} \tag{2}$$

And then we introduce the time slot assignment index C_t^m indicating whether service m occupies time slot t. Let $C_t^m = 1$ if time slot t is allocated to service m, otherwise $C_t^m = 0$. Note that each time slot can only be used by one service:

$$\sum_{m=1}^{M} C_t^m = 1, \forall t \tag{3}$$

Since based on time slot, the rate allocation is discrete in time which makes integral to summation in (1). By substituting C_t^m and (2) into (1), the constraints of the transmission rate that we must follow for service m is as follows:

$$\sum_{t=1}^{T} C_t^m r_m^t = T \times R_{mean,m} \geq T(\frac{L_m}{D_m T_{slot}} + \lambda_m L_m) \quad (4)$$

In order to reach the energy minimization, r_m^t should be as small as possible, which means the inequality on the right side must take the equal.

Combining all the time slots, we will obtain the overall energy consumption of the system:

$$\sum_{m=1}^{M}\sum_{t=1}^{T}(C_t^m \times P_{Total,t}^m)T_{slot} \quad (5)$$

Where $P_{Total,t}^m$ represents the overall power allocated to service m at time slot t, including transmission power and fixed circuit power, etc. With high data rate demand, transmission power is large enough to dominate the overall power. Closer to the actual network, we adopt the non ideal PA model, considering the influence of power amplifier that consumes the majority of energy.

Ensuring the QoS requirements of each service, the general form of this minimization problem can be formulated as follows:

$$Min \sum_{m=1}^{M}\sum_{t=1}^{T}(C_t^m \times \frac{\sqrt{\frac{\delta_t^2}{|h_t|^2}(2^{r_m^t}-1)\times P_{max}}}{\eta_{max}}) \quad (6)$$

$$Subject\ to \sum_{t=1}^{T} C_t^m r_m^t = R_{mean,m} \times T;\ \forall m \quad (7)$$

$$\sum_{m=1}^{M} C_t^m = 1;\ \forall t \quad (8)$$

$$C_t^m \in \{0,1\};\ \forall t,m \quad (9)$$

$$0 \leq r_m^t;\ \forall t,m \quad (10)$$

Here we adopt the TPA model:$P_{Total,t}^m = \frac{\sqrt{P_t^m \times P_{max}}}{\eta_{max}}$, where $P_t^m = \frac{\delta_t^2}{|h_t|^2}(2^{r_m^t}-1)$ on the basis of Shannon capacity.

We can see mapping of service and time slot is a combinatorial optimization problem, involving the 0,1 variables, and the number of optimization variables is enormous, so it is unable to give a analytical solution with closed form. For this NP-hard problem, our scheme employs genetic algorithm to iterate time slot selection and water falling algorithm to conduct rate allocation.

B. Time Slots Selection

GA is a powerful optimization technique based on the principles of genetics and natural selection and has been extensively applied to solve resource allocation problem in wireless networks which is usually NP-hard [10][13][14].

The structure of the chromosome representing slots selection scheme is described in Fig.3, where $C_m = (C_1^m, C_2^m, \ldots, C_T^m)$. As for GA's execution, we exchange

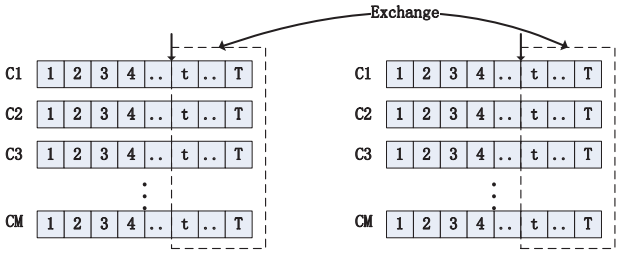

Fig. 3. Principle for crossover process of genetic algorithm in this paper

the rest sequences behind a site that is generated randomly for the crossover and the mutation is the reproduction for a chromosome. Note the constraint (8) is ensured but we cannot guarantee that every service at least have one time slot. If it happened, we need to give up this crossover and then repeat again. The better chromosome with high fitness will be more likely to be reserved according to Roulette Selection. Note that we save the best chromosome particularly before a new generation obtained.

C. Rate (Power) Allocation

Firstly, we assume that we have got a mapping relationship maybe not being the optimal through GA. Then we discuss the optimal rate allocation with the QoS constraints.

For a given mapping relationship of service m, (6) can be converted into:

$$Min \sum_{t=1}^{T}(\frac{\sqrt{\frac{\delta_t^2}{|h_t|^2}(2^{r_m^t}-1)\times P_{max}}}{\eta_{max}}) \quad (11)$$

$$Subject\ to \sum_{t=1}^{T} r_m^t = R_{mean,m} \times T \quad (12)$$

$$0 \leq r_m^t;\ \forall t \quad (13)$$

Utilize Lagrange multiplier method or convex optimization theory where:

$$J = \sum_{t=1}^{T}(\frac{\sqrt{\frac{\delta_t^2}{|h_t|^2}(2^{r_m^t}-1)\times P_{max}}}{\eta_{max}}) - \upsilon \sum_{t=1}^{T} r_m^t \quad (14)$$

Let $\frac{\partial J}{\partial r_m^t} = 0$, we can get:

$$\frac{\frac{\delta_t^2}{h_t|^2} P_{max} 2^{r_m^t} ln2}{\eta_{max}\sqrt{\frac{\delta_t^2}{|h_t|^2}(2^{r_m^t}-1)\times P_{max}}} - \upsilon = 0 \quad (15)$$

Since the demand for high data rate communication has been growing rapidly, r_m^t is fairly large, thus $2^{r_m^t} - 1 \approx 2^{r_m^t}$. So (15) can be transformed into:

$$\frac{\sqrt{\omega_t 2^{r_m^t} P_{max}} ln2}{\eta_{max}} - \upsilon = 0 \quad (16)$$

Where $\omega_t = \frac{\delta_t^2}{|h_t|^2}$, called noise-channel coefficient. If $BB = (\frac{v\eta_{max}}{ln2})^2 \frac{1}{P_{max}}$, thus $r_m^t = \log(\frac{BB}{\omega_t})$, we can get the following relationship considering constraint (12):

$$\sum_{t=1}^{T} \log(\frac{BB}{\omega_t}) = R_{mean,m} \times T \tag{17}$$

So we can resolve the water level as follows:

$$BB = \sqrt[TT]{2^{R_{mean,m} \times T} \prod_{t=1}^{T} \omega_t} \tag{18}$$

If the data rate obtained by Shannon capacity with the water level is negative, which is impossible in the actual system, we can infer that the time slot selection is wrong. It's known that the channel in poor condition will not be chosen according to the principle of water filling. So we should exclude the time slot where the data rate is negative and then recalculate the water level. Note that these excluded time slots will not be used by service m anymore.

D. Algorithm

In the algorithm, we generate the channel coefficient of each time slot randomly to simulate the real channel conditions and assume that the noise power spectral density is equal to 1, which are independent input variables. Our algorithm is described particularly as **Algorithm 1**. Note that the fitness function is designed to be the reciprocal of (6).

Algorithm 1 The mapped water falling algorithm

1: Obtain the transmission rate constraints from the QoS requirements of all services
2: **For all** $i \in (1, 2, 3, ..., Popsize)$ **do**
3: Initialize the time slot sequence of each service for chromosome i
4: **For all** $j \in (1, 2, 3, ..., M)$ **do**
5: Calculate the water level according to (18) for service j
6: Get the rate allocation according to the water level using shannon capacity formula for service m
7: **If** data rate is negative, let the rate as 0 and exclude the time slot whose allocation rate is negative. Turn to step 5
8: Calculate the fitness of the time slot sequence
9: **End for**
10: Add all the fitness together as the evaluating indicator
11: **End for**
12: Select and record the best allocation scheme
13: Obtain the next generation by crossover and mutation
14: **If** iteration reaches the threshold, end algorithm
15: **If else**, Turn to step 2 but skip step 3

IV. Simulation Results

We will get the optimal resource allocation scheme and the corresponding energy consumption by programming MWF algorithm in Microsoft Visual Studio. And then in order to evaluate the potential profit of our MWF scheme in cellular network, we adopt Monte Carlo simulation with Matlab in many cases to compare the energy performance with average rate allocation algorithm (ARA) and double genetic algorithm (DGA). ARA refers to that the data rate demand is distributed to each time slot equally, while DGA both applies genetic algorithm to finish time slot selection and rate allocation.

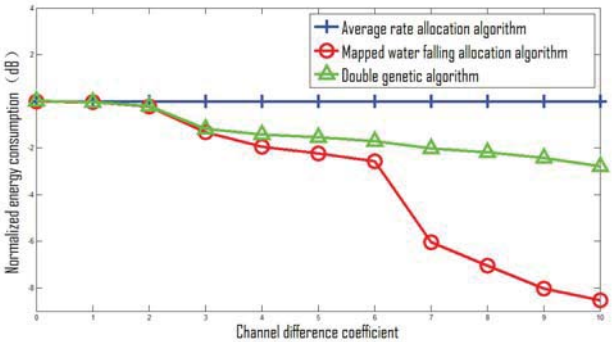

Fig. 4. Normalized energy consumption versus the channel difference coefficient (16 time slots and 2 services)

To further control the difference of channel coefficient, the channel difference coefficient $PathLossCoeff$ is also introduced. So we can get the following method:

$$|h|^2 = rand^{PathLossCoeff} \tag{19}$$

Where $rand$ is a random number between 0 and 1.

In Fig.4 and Fig.5, the vertical axis is normalized energy consumption which can be understood as the optimization degree compared with ARA scheme.

From Fig.4 we can find that the scheme we proposed has the best energy performance compared with the two others. And with the increase of $PathLossCoeff$, the optimization degree of MWF becomes better. All the three schemes reach the same performance when $PathLossCoeff$ is equal to 0 which means all the channel conditions are the same especially. The reason why appears such a phenomenon is that the channel conditions play a more and more important role in rate allocation with the increase of $PathLossCoeff$.

Fig.5 evaluates that MWF is better than the two other schemes in terms of energy. At the same time we can observe that with the increase of abscissa, MWF's performance will be getting worse while ARA's performance first will decline and then will ascend. In the end, when the service number and the time slot number are the same, only one time slot will be allocated to each service. So the performance of the three schemes are identical just depending on time slot selection. As for MWF, due to the service number increasing, the average time slots that can be allocated to a single service is reduced, i.e. the parallel channels are less, which causes the decrease of the diversity degree. As is known that each service is independent with others, the performance reduction of single service will lead to a falling of the whole scheme performance. The probability that DGA can find the optimal

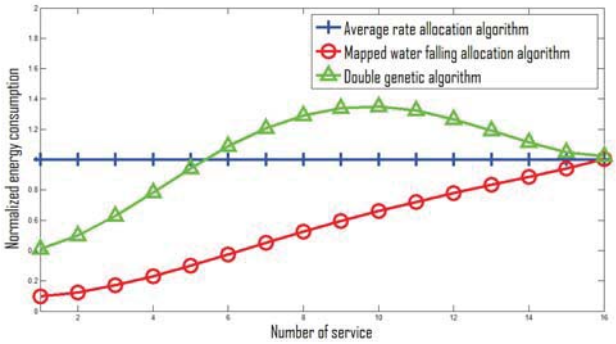

Fig. 5. Normalized energy consumption versus the number of service (16 time slots and $PathLossCoeff$ is equal to 6)

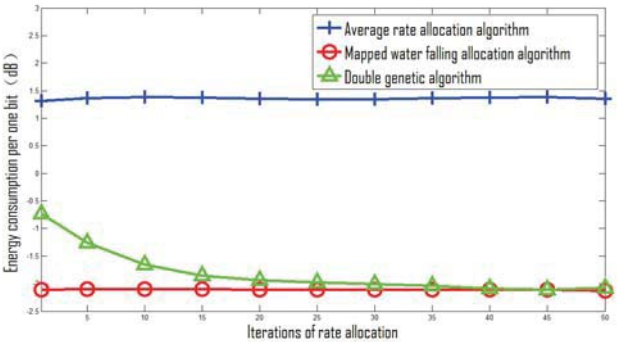

Fig. 6. Energy consumption per one bit versus the iterations of rate allocation (16 time slots, 2 services and $PathLossCoeff$ is equal to 6)

solution is determined by the number of feasible samples. According to the knowledge of permutation and combination, the mapping patterns first increase and then decrease, identical to the tendency of DGA's curve.

In Fig.6, the vertical axis is energy consumption per one bit in the form of decibel. We can see that the energy consumption per one bit of DGA are reduced and reach to the MWF's with the increase of iterations of rate allocation. The gap on the performance between DGA and MWF is getting smaller because the solution that DGA can find becomes better and better. But when the iterations exceed a certain threshold value, DGA can find a optimal solution like MWF and the performance will become stable, implying MWF is the best. Note that DGA tends to converge with evolution and iteration.

V. Conclusion

In this paper, we proposed a novel MWF scheme to separate the complicated resource allocation problem without closed form analytic solutions into two simple subproblems intelligently. Without avoiding the NP-hard problem for mapping combination between services and slots, time slot selection problem is presented by genetic algorithm rightly. Having Deduced the water falling principle under non ideal PA model, the closed form solution for the rate allocation subproblem was obtained normally. Experimental simulation results can verify the great energy performance of our proposed scheme compared with the two others, ARA and DGA.

The time slot selection adopts genetic algorithm that is randomly and complex. In the future, we will make effort to replace the method to another definite and simple one.

***Abstract*— A mobile healthcare protocol, which is capable of collecting data readings of patient's physical health parameters (e.g., EEG, ECG signals etc.) and sending them to physician through a wireless channel continuously over the service provider infrastructure network or the Internet, is of extreme importance in the case of diagnosing chronic diseases. To serve this purpose, one of the many problems arises, that is the storage of large amount of data associated with these vital readings like EEG, ECG etc., as well as their effective transmission over wireless network. In this paper, we present a mobile healthcare protocol that comprises of three different layers in which an efficient algorithm is proposed in layer II that allows near lossless compression of multi-channel electroencephalogram (EEG) signals; and the same algorithm will run in layer III in the reverse way for the perfect reconstruction of these compressed signals in the real time. As the EEG signal is highly uncorrelated in nature, the modified Run Length Encoding (RLE) and ASCII encoding techniques are used together to compress it. The EEG compression algorithm is implemented using Java. The results obtained are found to perform better when compared against existing EEG compression algorithms in terms of percent mean square difference (PRD), compression ratio (CR) and execution time.**

Keywords— Mobile; Health; Compression Algorithms; EEG; Wearable Health devices; Run-Length encoding.

I. INTRODUCTION

Mobile healthcare is fast growing in the domain of today's pervasive healthcare and wireless health monitoring. One of the main aspects of this mobile healthcare is to monitor different physical health parameters (e.g. EEG, ECG) of the patient using wearable health monitoring devices, to process them in their handheld device like smart phone and to send them to physician over wireless network infrastructure or Internet.

The mobile healthcare protocol can be divided into three major layers, which are shown in Fig. 1. The layer I consists of health monitoring devices, like ECG and/or EEG monitor and/or few other devices attached to a patient's body. These wireless health monitoring devices can build a network called wireless personal area network (WPAN). These devices can continuously send data to a registered (paired) device using a secure channel via Bluetooth.

The layer II consists of application stack which contains three components: 1) the data receiver to receive data transmitted by health monitoring devices, 2) the compression algorithm to compress data into a short ASCII message and 3) the data transmitter which sends encoded data stream to registered physician or hospital by identifying their attributes.

The layer III contains two components. The first component has two functions to receive encoded data through wireless network infrastructure and decompress them into original wave forms. The second component is a decision counter that will perform tasks based on the information extracted from decompressed data.

The main challenge to develop this architecture lies in collecting the large amount of physical health data and successful transmission of these data to the physician in real time. Compression technique is imperative to ease and solve this problem. To address the problem of compressing EEG data in real time, we propose a compression algorithm to solve this problem in the mobile healthcare protocol.

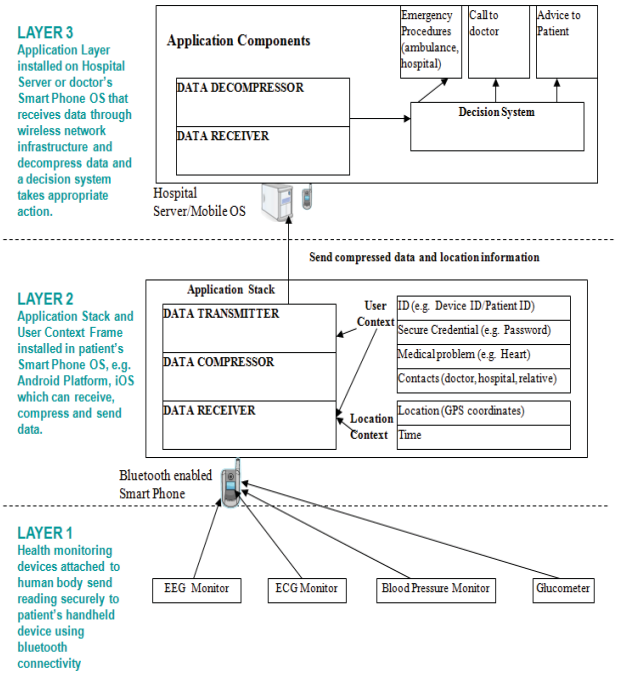

Fig. 1. Mobile Healthcare Protocol

The earlier research works had been done on ECG signal compression techniques [1], while the compression technique of EEG signal was a comparatively unexplored area. All the existing techniques [2], [5]-[7], [11]-[12] did not take into account network design parameters like

bandwidth limitation, wireless communication and packet drops, which became a design issue in our proposed protocol when EEG waveforms needed to be continuously transmitted in real time. Moreover, for highly uncorrelated signals like EEG signals, the existing techniques could not achieve high compression ratio. On the contrary our proposed compression algorithm running in layer II is capable to carry out encoded data in real time with a better compression ratio.

For ECG waveforms there is a well-defined QRS region that can be targeted for compression but for EEG there is no such corresponding feature. Also the voltage values span a much wider range for EEG. During our analysis of the EEG voltage values, we notice that the coefficients are sparse for higher orders of magnitude. We apply this feature and use an optimized combination of RLE and Digit Grouping techniques to achieve higher compression ratios. We use ASCII for encoding the compressed signals because of its narrower range of values and its ability to be sent easily over basic mobile wireless infrastructure using low network bandwidth, e.g., using simple text SMS messaging.

Section II describes the attributes of the EEG compression technique; section III describes our proposed algorithm for EEG data compression and reconstruction; section IV presents our simulation strategy and results obtained for the proposed system and compares its performance with the existing algorithms. Finally, section V concludes the paper and discusses future scope of the work.

II. ATTRIBUTES OF EEG COMPRESSION TECHNIQUE

In order to define compression algorithm stated in layer II, we need to describe few attributes of EEG.

A. EEG Overview

EEG is a graphic representation of electrical activity of brain along the scalp formed due to the constant exchanging ions by brain cells i.e., neurons with the extracellular milieu [3]. Scalp EEG activity shows oscillations at a range of frequencies [4]. The different frequency bands and their attributes are discussed below:

Delta: Its frequency range is 4Hz or below. It is highest in amplitude.

Theta: Its frequency range is between 4 Hz to 8 Hz and is classified as slow activity.

Alpha: Its frequency range is between 8 Hz to 13 Hz.

Beta: It has a frequency 13 Hz to 30 Hz and is classified as fast activity.

Per medical science, frequency bands 4Hz to 13 Hz are acceptable for clinical diagnosis. Below 4Hz and above 13Hz, the EEG readings are treated clinically normal. In our work, we will consider entire four bands for compression algorithm.

B. EEG Data Characteristics

A study of EEG Digital Data shows signal values that have a range in orders of magnitude from 10^{-6} to10^{-6} after converting to integers. Representing each number from such a large range would need at least 40 bits (41 bits considering sign bit representation). Real number representation would need even more space. In addition, EEG readings needs to be combined along with the patient's current context, location and medical information so that the health-care provider (doctor, hospital) can correctly correlate patients with EEG readings when there is transmission from multiple patients and take appropriate action specific to the patient.

In order to effectively transmit this data in real time, effective compression must be used so that a meaningful window of data can be sent in real-time along with the patient's information. Careful analysis of the EEG voltage values reveals that these are sparse in higher orders of magnitude than in lower orders. This property was used in the compression algorithm as described in the next section. An ASCII 8-bit representation is used for representing the compressed signal because of its low range of values from 0 to 256 and also the ability to easily send ASCII data over existing mobile infrastructure like SMS.

C. Parameters for Measuring Effectiveness of an EEG Compression Algorithm

The effectiveness of an EEG compression technique is described in terms of:

(a) Compression ratio (CR) is the ratio of the size of the original data (ORG) to the compressed data (CMP):

$$CR = \frac{size\ of\ ORG}{size\ of\ CMP}$$

(b) Execution time, the processing time is required for compression and reconstruction of EEG data; and

(c) A measure of error loss is often measured as the percentage mean-square difference (PRD). The PRD is calculated as follows:

$$PRD = \sqrt{\frac{\sum_{i=1}^{n}(ORG(i)-REC(i))^2}{\sum_{i=1}^{n}(ORG(i))^2}}$$

where ORG is the original signal and REC is the reconstructed signal. The lower the PRD, the closer the reconstructed signal is to the original EEG.

III. PROPOSED ALGORITHM

The *objective* of our algorithm is to encode the EEG data set in a specific format so that a high CR can be achieved (i.e., in layer II) and obtained exact reconstruction of those encoded data keeping the PRD as low as possible (i.e., in layer III). This proposed algorithm encodes the whole set of EEG data in ASCII format i.e., it maps all the EEG data into a decimal range of 0 to 255 keeping the loss as low as |.050| millivolts per sample.

The *difficulties* encountered for mapping the whole EEG data set into ASCII set are:

a) Range: EEG data sets have a long range of voltage values from microvolts to millivolts.
b) Uncorrelated dataset: The voltage values of the EEG dataset are highly uncorrelated.
c) Special ASCII characters: At the time of converting the voltage values of EEG data set, some special characters like 10 (Line feed), 13 (carriage return), 26 (substitution) or 255 (blank) occur problems. Those numbers can be printed in character form but at the time of data reconstruction of these values (13, 26 and 255) will be considered as 'End of File' by the compiler and the program will get terminated. The algorithm is designed to overcome the problem.

Careful investigation of EEG voltage values over a random period of one or two minutes reveals that the

numbers of high value data are less on the contrary, the low value data are higher in number. We have used this *sparse* nature of EEG data set to achieve high CR.

The proposed algorithm has two sections: A) the compression algorithm (i.e., in layer II) and B) the decompression algorithm (i.e., in layer III). Both of them are discussed in detail below.

A. Compression Algorithm

This *compression algorithm* consists broadly of the following steps:

1) From the continuous stream of EEG voltage values which are taken at 3-4 millisecond intervals, a window of length two seconds is picked up. This window contains multiple voltage values.
2) Let us consider −462.317 as an arbitrary sample voltage value picked up from this window. This can be expressed as
$-1 \times (4\times10^{2} + 6\times10^{1} + 2\times10^{0} + 3\times10^{-1} + 17\times10^{-3})$.

−	4	6	2	.	3	17
Sign	A3	A2	A1	_	B1	B2

Here, A3, A2, A1 and B1 denote the coefficient (1 digit each) of the 2^{nd}, 1^{st}, $0^{th,}$ -1^{th} power of 10 respectively while B2 denotes the coefficient (2-digit) for the -3^{rd} power of 10. *Sign* denotes the sign of the sample voltage. The coefficients and signs for all the voltage values in the selected window are stored in six separate arrays as described below. While the arrays for A3, A2, A1 and B1 contain the actual coefficients, the arrays for B2 and *SignBits* are binary, containing just 1 or 0 bit.

3) *Encoding SignBits and B2*: The *SignBits* and B2 arrays are 8-bit binary arrays initialized so that the last (least significant) bit is always '0' and the first two (most significant) bits are always '1'. The remaining five bits contain values for the next five voltage values.

SignBits is encoded according to the following rule.

SignBits[i] = 1 if i^{th} coefficient < 0
SignBits[i] = 0 if i^{th} coefficient ≥ 0

B2 is encoded using the following rule:
For the i^{th} voltage value,
If the coefficient B2 > 50 then B2[i]=1
Else B2[i] = 0
This ensures the maximum error per sample is .05 mV.

The 8-bit array approach ensures that the decimal equivalents of *SignBits* and B2 are always in the range 192 (11000000) and 254 (11111110). This range does not have any special ASCII characters, so it is not required to apply ASCII correction (discussed later).

4) *Encoding A3, A2, A1 and B1* arrays: These arrays (not 8-bit) are subjected to an optimized combination of *Grouping Technique* and *RLE* to convert them to their corresponding *grouped* values. Let each of the initial coefficient arrays for A3, A2, A1 and B1 be termed as *IntArr* and the corresponding grouped arrays termed as *GrpArr*. The conversion is iteratively carried out for each of the four coefficient arrays by applying either the grouping or the RLE technique as described below. Starting from 1^{st} position (1^{st} voltage value) of *IntArr* and continuing till the last but one position. Let i denote position in *IntArr* and j denote position in *GrpArr*. Both pointers start from 0 and advance as mentioned below.

(a) If the i^{th} element of *IntArr,* i.e., IntArr[i] is non-zero, then apply the *Grouping Technique*:

Grouping Technique:
If (IntArr [i] × 100 + IntArr [i+1] × 10 + IntArr [i+2]) < 256
Then
GrpArr[j] = (IntArr[i] × 100 + IntArr[i+1] × 10 + IntArr[i+2]);
Else
GrpArr[j] = IntArr[i] × 10 + IntArr [i+1];
End of if
If position (i+2) falls outside IntArr, the Else part applies.

(b) If *IntArr*[i] = 0 then apply the *Modified RLE Technique*:

Modified RLE Technique:
We count the number of *consecutive occurrences of zero* in *IntArr* starting from the i^{th} position and moving right. Let this count be *OccurZero.* Then execute the following iterative loop routine:

Label:
If (OccurZero = 1) Then
GrpArr[j] = 1; EXIT;
Else If (OccurZero = 2) Then
GrpArr[j] = 2; EXIT;
Else If (OccurZero = 64) Then
GrpArr[j] = @;
GrpArr[i+1] = 6;
GrpArr[j+2] = 4; EXIT;
Else If (2 < OccurZero ≤ 255) Then
GrpArr[j] = @;
GrpArr[j+1] = OccurZero; EXIT;
Else If (OccurZero > 255)
GrpArr[j] = @;
GrpArr[i+1] = 255;
OccurZero = OccurZero − 255;
Goto *Label*;

Since the decimal equivalent of @ is 64, so a *special treatment* is required when OccurZero is 64.

5) Once the IntArr arrays for A3, A2, A1 and B1 have been completely traversed, five grouped voltages are picked iteratively from the *GrpArr* array and *ASCII correction technique* (described later) is applied on each of them. An eight bit array named *CorrPos* having the pattern 11xxxxx0 (same as for SignBits and B2) is used to store the ASCII correction status of the five voltages based on whether they need ASCII correction or not:
CorrPos [i] = 1 if i^{th} *GrpArr* needs correction

CorrPos [i] = 0 if i^{th} *GrpArr* does not need correction.

Because of the structure of the CorrPos, B2 and SignBits arrays, no ASCII correction is needed and each can store data for five voltage values.

6) Finally, the decimal values of these seven arrays (*GrpArr*s for A3, A2, A1 and B1 and arrays for B2, *SignBits* and *CorrPos*) are converted to their equivalent ASCII characters and sent as described below:

The structure for each group of five voltages is:

GrpArr for A3	*GrpArr* for A2	*GrpArr* for A1	*GrpArr* for B1	*B2*	*Sign Bits*

The structure of the CorrPos for a group of five voltages:

CorrPos for A3	*CorrPos* for A2	*CorrPos* for A1	*CorrPos* for B1

Five such voltage values are sent serially along with the four CorrPos arrays for A3, A2, A1 and B1. The following structure is repeated for all the groups of five voltages that were picked up initially as part of the window:

1st group of 5 voltages	1st CorrPos	2nd group of 5 voltages	2nd CorrPos	…..so on for all groups

Special ASCII Correction

The ASCII correction scheme converts special characters into printable characters using the following steps:

New value = value-1 if value in {10, 13, 26, 255}
= value+32 if 128 ≤ value ≤ 159
= value otherwise

Rationale: ASCII values {10, 13, 26, and 255} are considered as end of line during program execution which therefore terminates if it encounters these. All ASCII values from 128 till 159 are interpreted as '?' or 63 when converting back to decimal and so are unusable. All the remaining ASCII values from 0 to 255 are correctly interpreted, so they *do not need* special ASCII correction.

B. Decompression Algorithm

During decompression we simply follow our proposed compression algorithm *in the reverse order.* The steps are:

1) Decomal conversion: The received ASCII characters are first converted to their decimal equivalents to get back five sets of A3, A2, A1 and B1 and the values for B2, Signbits and CorrPos.

2) Reverse ASCII Correction: The CorrPos array is used to determine whether to apply reverse ASCII correction on A3, A2, A1 and B1 and then apply the reverse correction for such cases (increment values 9, 12, 25, and 254 by 1 and decrement by 32 otherwise).

3) Ungrouping: The A3, A2, A1 and B1 GrpArr arrays are ungrouped (applying reverse grouping/RLE) to get back the initial *IntArr* values, i.e. the coefficients A3, A2, A1 and B1. Let positions in *GrpArr* be denoted as i and those of *IntArr* be j. The following reverse generation technique is applied iteratively (pointer positions are advanced by 1 for both unless otherwise mentioned.)

Reverse Grouping/RLE Technique:

- If GrpArr[i] = 1, IntArr[j] = 0
- If GrpArr[i] = 2, IntArr[j] = IntArr[j+1] = 0. Advance j by 2
- If GrpArr[i] = 64 (character '@'),
  - If GrpArr[i+1]=6 and GrpArr[i+2]=4, fill zeroes in IntArr[j] to IntArr[j+63]. Advance i by 2 and j by 64
  - If GrpArr[i+1]=255, fill 255 + GrpArr[i+2] zeroes in IntArr. Advance i by 3 and j by 255 + GrpArr[i+2]
  - Else fill GrpArr[i+1] zeroes in IntArr.. Advance i by 2 and j by GrpArr[i+1]
- If GrpArr[i] > 100 fill IntArr[j], IntArr[j+1] and IntArr[j+1] with the hundreds, tens and unit place in GrpArr[i]
- If GrpArr[i] > 10 fill IntArr[j] and IntArr[j+1] with the, tens and units places in GrpArr[i]
- Else IntArr[j] = GrpArr[i]

4) Sign Retrieval and Coefficent Conversion: Finally the SignBits array is used to get back the original signs and coefficients A1…B2 are multipled by corresponding coefficients of ten to get back the original voltage values.

.

IV. SIMULATION STUDY

In this simulation study, we test the performance of compression (layer II) and decompression (layer III) techniques described in proposed algorithm in the mobile healthcare protocol.

We assume in the simulation study that EEG data is transmitted from EEG monitor device to patent's handheld device through Bluetooth that is layer I function in mobile healthcare protocol. The compression technique part of our algorithm will run in patient's handheld device to encode the data that is the layer II Application stack function. Next, this encoded data will transmit to physician's handheld device or into hospital server through wireless service provider infrastructure or through Internet. In layer III, the reconstruction of the data will be done, that is part of our proposed algorithm, and subsequently decision system will take the next action. This study of performance for each layer of mobile healthcare protocol will be our future work.

In this work, we only validate and demonstrate the performance of compression and reconstruction technique in our proposed algorithm for EEG data that is implemented in the JAVA version 7. Next, this algorithm has been tested with ten minutes of EEG data waveform stored digitally in the MIT-BIH database [10]. The EEG signals are sampled at 256Hz (i.e., 256 samples/second). So, ten minutes of EEG data contain total 1.536×10^5 numbers of samples. After going through the compression algorithm these ten minutes of EEG long data are converted into a printable stream of ASCII characters and are printed in a file. This file has subsequently been used for the input to the decompression algorithm and EEG stream is finally reconstructed. The original EEG data stream and the reconstructed EEG data stream are then compared to calculate the loss.

To test the performance of proposed compression technique for EEG, ten datasets are randomly selected from

CHB-MIT Scalp EEG database [10] and given input to our algorithm. Subsequent to compression, the databases are reconstructed by our algorithm too. The results thus obtained are shown below in Table 1.

TABLE 1: Compression Results

Data Sets	**Compression Results**		
	Signal Record	***CR***	***PRD (%)***

Average		**3.892**	**0.080**

CR and PRD for different datasets are graphically shown below in Fig. 2.

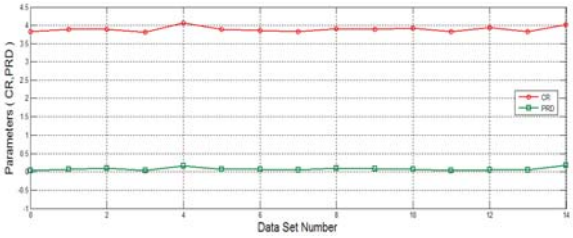

Fig. 2. CR and PRD for different datasets

The figures shown below are original signals (Fig. 3, 5) and reconstructed signals (Fig. 4, 6) using proposed algorithm.

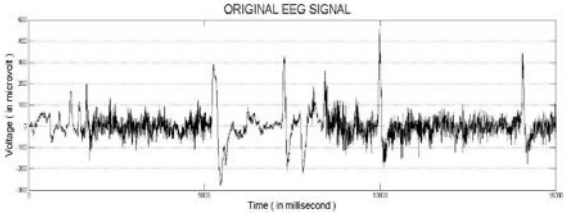

Fig. 3. Original EEG signal (Record: chb01/chb01_01 FP1-F7)

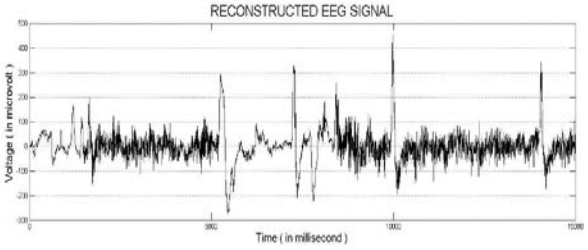

Fig.4.Reconstructed EEG (Record: chb01/chb01_01 FP1-F7)

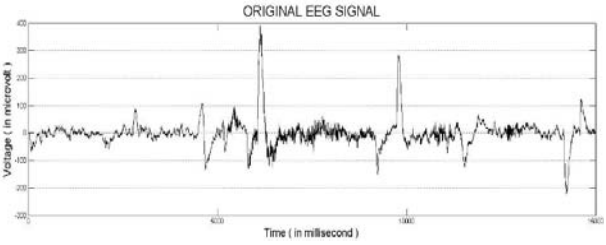

Fig. 5. Original EEG signal (Record: chb01/chb01_05 F7-T7)

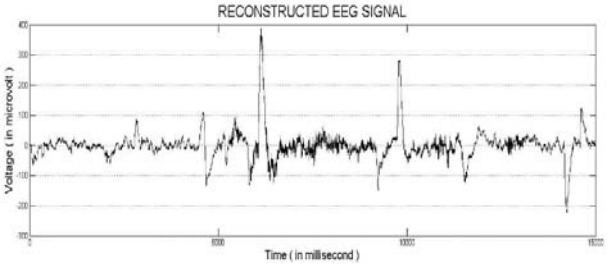

Fig. 6.Reconstructed EEG signal (Record: chb01/chb01_05 F7-T7)

We can see from the figures that for two quite different patterns of original EEG signals (Fig 3 and 5), the reconstructed EEG signals (Fig. 4 and 6) faithfully reproduce the original signals so that the doctor can make an accurate diagnosis. This is especially important for EEG signals as these can have many different patterns as opposed to ECG signals which have a relatively smoother and more consistent pattern.

TABLE 2: Performance Comparison

Algorithms	**CR**	**PRD (%)**
Vector quantization with collapsed Huffman tree [2]	2.63	~0
Adaptive error modeling scheme [8]	3.23	-
SLP predictor with error modeling and arithmetic coding[5]	2.72	-
KLT transform[6]	2.84	~0.6
Wavelet-SPIHT[7]	2.046	~0.5
SPECK[9]	1.73	0.66
BISK[9]	1.74	0.67
Our proposed algorithm	**3.892**	**0.080**

For earlier data compression techniques used for EEG compression like Huffman coding and Vector quantization [2] with collapsed Huffman tree, Linear and Adaptive predictor, RLSL filter, Artificial Neural Network predictor and other transformation techniques like KLT, DCT, DWT [5]-[7], [9], the execution time varies from medium to high as most of them require more buffer size for storing and filtering. So, it is difficult to implement them for real time applications. Whereas our algorithm has a negligible PRD (~0.1%), high CR and most importantly it can be executed on real time. Table 2 has shown the performance comparison among various compression algorithms including our proposed algorithm.

V. Conclusion and Future work

We have presented a mobile healthcare protocol comprising of three different layers with the main focus on layer II where we have proposed a near lossless compression of multi-channel EEG signals. We have used an algorithm which is a combination of a modified version of RLE and ASCII encoding techniques to compress and reconstruct the EEG signals. We used the idea of space and time management to compress a continuous stream of EEG signals and to reconstruct that stream with very low distortion. We have made an assessment of the quality of the reconstructed signal and observed that it is robust both when visually inspected and also in terms of the CR and PRD values remaining constant for multiple data sets.

In our future work we will explore the possibility of applying faster variations of compression techniques such as compressed sensing along with the use of specific templates or waveforms which can be dynamically determined and applied based on the characteristics and type of signal being compressed, e.g. EEG, ECG or EMG. We would design means of applying our three layer protocol stack in the case of large number of senders streaming signals to the same mobile device using dynamically changing, unreliable networks.

***Abstract*—An unprecedented big earthquake and tsunami happened on March 11, 2011 called Great East Japan Earthquake, more than 20,000 people passed away by this disaster. At that time, because of the communication infrastructure also damaged and congested, most people in the disaster area did not use communication system. From these lessons, the resilient, robust and early recoverable network system is required. We have developed regional resilient network system called NerveNet. In this paper, the requirements for the network at the disaster situation are organized, and NerveNet system architecture, platform and example applications are introduced. A NerveNet system pilot test has started in Onagawa town, Miyagi prefecture, hit by the tsunami. Its pilot testing and disaster drill trial using NerveNet system and applications are briefly introduced.**

Keywords— NerveNet, mesh network, disaster resilient, smart city, disaster drill, Onagawa town, information sharing.

I. INTRODUCTION

More than 20,000 people passed away by the huge earthquake and tsunami at the great east japan earthquake in March 11, 2011. The lifeline that not only electricity, water, gas, but also mobile communication and Internet communication were cut off in the affected area. Because of the damage of the communication system, people could not confirm his/her family's safety in the affected area. Emergency call was also unavailable at that time. Roads, railroads and highway also destroyed over a wide area, so that the arrival of the emergency vehicle and rescue team delayed. Food and aid and medical supplies also delayed by the transportation disruptions, it leads the secondary damage. If the disaster damage situation grasp had been accurately done and regional information sharing and communication could be available by the resilient information and communication system, secondary damage might be minimized. From this viewpoint, the communication is one of the lifeline infrastructure should not be without.

The mobile communication infrastructure is extended architecture based on the telephone system, so its network topology is tree based topology, and also centralized controlled and management system is adopted. For these reasons, if the branch nodes of the backhaul network has damaged, the whole leaf area is affected by this damage. In addition, the centralized server manages the communications, so the admission control is required when the number of communication request is over the processing capacity of the centralized server. Actually immediate after the earthquake on March 11, 2011, the mobile operators in Japan applied call restriction ratio up to 90%. For the reason of this restrictions, the mobile phone communication is hardly used not only the disaster affected area but also whole area in Japan for several days.

From this background, we have been developed disaster resilient regional area information and communication platform called "NerveNet"[1]-[4], which can provide robust network and application services without depending on the server system in the core network or the Internet. NerveNet base station can provide information sharing application service and peer to peer communication service standalone, and if two or more base stations are interconnected each other, they work together distributed manner.

II. REQUIREMENTS FOR THE EMERGENCY COMMUNICATIONS

The communication requirements for under the disaster situation is depend on the target users. Our system is targeting to the users as follows.

A. Requirements for the general users

It is the best for the general users to use ordinal mobile communication service without any inconvenience even the disaster happened. These communication infrastructures are maintained and operated by mobile service operators or mobile carriers. To increase the network redundancy and robustness, mobile carriers have to invest to the infrastructure more. But it takes large amount of costs to strengthen these infrastructures, which is over specification for general use case. The decision to construct redundant and robust network system is up to the mobile carrier's effort. Usually, enhancing the system redundancy and pursuing the profit are contrary to each other, so excessive capital investment and redundancy endurance that is not contributed to service quality improvement cannot be expected to mobile carriers.

B. Requirements for the self-managed network by local government

Some local governments construct their own self-managed regional network to ensure the communication system

redundancy. Most of their self-managed regional network infrastructure is closed network only for the local government use, and actual utilization ratio compare to its bandwidth is very low. But its maintenance fee occurs constantly. For this reasons, the effect that can be obtained from the capital investment to the private network construction is very limited in peacetime. To pay high insurance and to build a self-managed private network is equivalent. Some local governments are renting their own fiber optic cables to a network operator, which is so called public build and private operate scheme. But this scheme is limited to the physical network infrastructure construction and renting. It is demanded that the same physical network infrastructure can be isolate logically, and logical network resource can be rent to the network operator virtually to accelerate the self-managed network utilization improvement.

C. *Requirements for rescue and disaster relief team*

The ad-hoc communication system is necessary for the rescue and disaster relief tem such as fireman, police, and army. The team members have to share or report the information to the head quarter or commander, and they have to receive the instruction from head quarter without depending on an existing network infrastructure because it is not always exist in their activity area. Usually, MCA radio system is used for their communication. This system is very simple, but the communication channels are limited. So they have to care about the channel interference. Furthermore, MCA radio system is voice broadcasting, so it is useful for information sharing or one to multiple communications such as instruction message dissemination from a commander to members. But it is not suitable for the communication such as peer to peer communication and many to one communication. In addition, MCA radio system is specialized to the voice communication, and only very short data communication such as GPS data broadcasting is supported. Therefore, not only voice broadcasting but also ad hoc, peer to peer, high bandwidth data communication system is required.

When the rescue team or disaster relief team want to share photos, videos, and their location information among the team, the information sharing server system is required. Usually, most information sharing applications are depending on the specific servers on Internet. When they want to operate the same system without having a connection to Internet, some application server system has to be operated inside the ad-hoc network. But considering the ad-hoc network instability, network connectivity to the specific server might be unstable and disconnected some time. Considering this situation, information sharing system with multiple servers should be operated distributed manner to be robust to the network isolations. By employing this architecture, even when a certain disaster relief team is isolated to the other team, they can still share the information inside the team by using local information sharing server. When they merged to the other team, the sharing information also merged to the other team, and the distributed server continue working as a part of the one big information sharing system.

D. *Requirement for the network operators for the disaster recovery*

When a big disaster was happened and several network infrastructures has damaged, network operator have to recover the system as soon as possible. To recover complete system takes long-time, so temporal and early recovering technology is required even the service is conditional. For this use case, generic and reconfigurable network interface and virtualization technology are required.

III. NERVENET OVERVIEW

From the requirement above, we are designing a new regional distributed network architecture called NerveNet. NerveNet system, which is consist of several NerveNet base stations. Fig.1 shows a NerveNet base station image and specifications. NerveNet base station is consist of a VLAN intelligent switch and CPU board that has flash storage device (CF and SD card) and RAM disk. Linux OS is running on the CPU board, several distributed server and database systems are running on the OS. NerveNet base station can provide information sharing application service to mobile terminals by stand-alone. If several NerveNet base stations are interconnected each other, each base station automatically detects the neighboring base stations and they begin to co-operate with each other. Finally, individual NerveNet systems are merged to one system autonomous and distributed manner. For this characteristics, NerveNet system provides a thought of regional cloud platform which has redundant network functions, name/address resolver function, distributed storage, database, and processing functions. To be able to operate NerveNet system by stand-alone, all server functions such as DHCP, DNS, SIP, etc., are embedded inside the base station with customizing to cooperate with other base stations.

NerveNet system can use standalone network system, but if one or more base stations are connected to the Internet, NerveNet can also provide redundant Internet access backhole

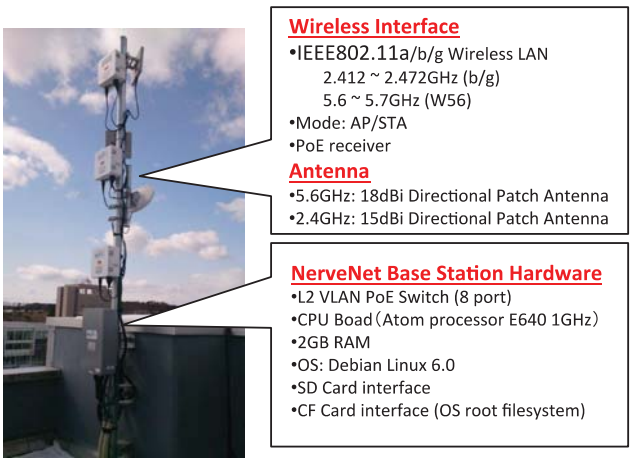

Fig.1 NerveNet base station hardware specification

network.

NerveNet system functions are categorized to two parts. One is application service platform that is including distributed

servers and database functions, database synchronization functions, and name/address resolver and P2P communication functions. The other is network service platform that is including VLAN switch controller, reliable flooding, IP address assignment, neighborhood link sensing, mesh topology monitoring and management. The architecture function block inside NerveNet base station is shown in Fig. 2, and these two service platform functions are show in table1.

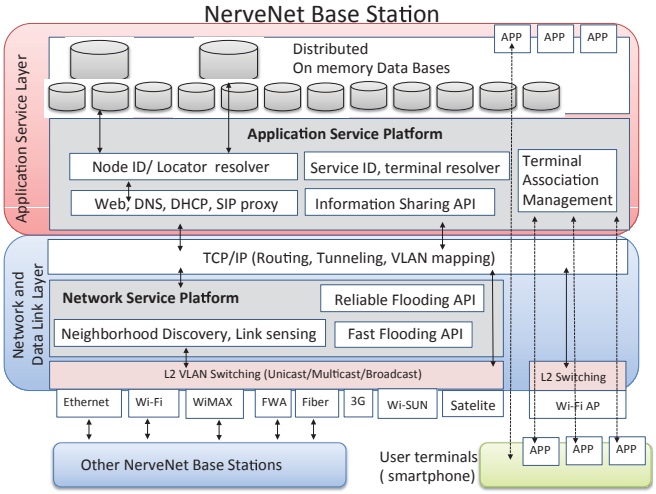

Fig. 2. NerveNet base station architecture function block

Table 1. Base station service platform functions

application service platform	IP address allocation (DHCP)
	Name resolution (DNS)
	Peer to Peer communication (SIP Proxy)
	Distributed database system
	Distributed server system(Apatche)
	Database synchronization service
	Terminal association management service
Network service platform	VLAN switch control
	Multiple VLAN path maintenance and path selection
	Traffic control and management
	Reliable flooding and multicasting
	Autonomous link sensing and path switching
	Multi-homing
	Network virtualization (L2 tunneling)

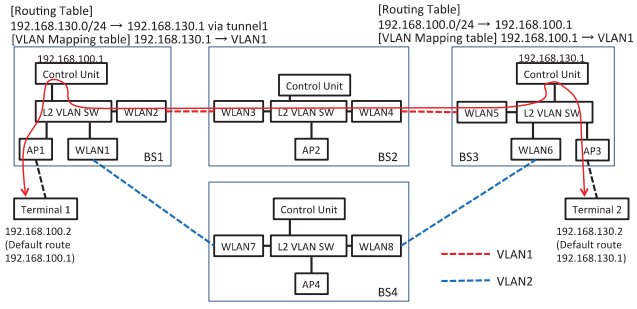

Fig. 3. NerveNet routing and switching mechanism

IV. NETWORK SERVICE PLATFORM

NerveNet network service platform provides routing, switching management and flooding functions. Total network is managed from one management PC that is called Network Manager (NM). The NM doesn't have to connect at all times. NM manages the network configuration when network topology has changed, or new base station has been installed. When a NM is attached to the NerveNet base station, whole network topology and link information can be monitored from the NM. Then, NM calculates multiple and redundant VLAN tree topology from the mesh network topology, and the multiple VLAN configuration set based on the calculation result are flooded to all base stations. All base station which is received this configuration apply to its own VLAN switch. Finally, multiple VLAN tree path is constructed over the mesh topology. NerveNet base station select minimum cost VLAN tree to communicate with each base stations.

Fig.3 shows an example of NerveNet base station routing and switching mechanism. Each base station acts as an IP router for mobile terminals. Each base station assigned different subnet, which is automatically assigned based on the base station ID. When BS1 received IP packet from a terminal, BS1 lookup its own routing table and then forward it to the BS3. At the same time, BS1 lookup its own VLAN mapping table, and VLAN 1 tag is attached to the frame and transmitted to the VLAN switch. The frame is switched through BS2 based on MAC address learning table, and reached to BS3. BS3 finally forward the IP packet to the destination terminal. When BS1 detect the link disconnection between BS2, then BS1 autonomously update VLAN mapping table to BS3 as VLAN2 without depending on the NM.

V. APPLICATION SERVICE PLATFORM

NerveNet application service platform provides many functions as API for smartphones. To explain NerveNet application service platform functions, two example applications is introduced as follows.

A. *Extension telephone application*

The extension telephone application uses NerveNet peer to peer communication functions. When a smartphone that is installed this application is connected to a NerveNet base stations, base station assigned an IP address to the smartphone by DHCP protocol. As a NerveNet base station is periodically broadcasting original beacon messages, so the application in the smartphone can notice that now it is connected to NerveNet base station, and then application register its own IP address and SIP URI to the associated base station. (When the application installation, unique SIP URI is pre-assigned to the application.) By receiving this registration massage, base station registered a pair of SIP URI and IP address to its own distributed database. Base station's distributed database is synchronized to the other base stations, so this information is shared among base stations. When a user wants to make a call using this extension telephone application, the user selects one destination SIP URI from its address book and calls up. Then "INVITE" SIP massage is transmitted to the associated base

station by caller application. Base station is act as SIP proxy, so it received INVITE message, then it looks up IP address associating to SIP URI and forward it to this IP address. When callee application received INVITE message, then "180 RINGING" message is replied and bell rings. When callee received the phone call, "200 OK" massage is transmitted to the caller, and then peer to peer voice communication starts. These IP address resolution and peer to peer session initiation API is provided to the application developer.

B. Information sharing application

Information sharing application uses distributed database inside NerveNet base station. NerveNet application service platform also provides database synchronization mechanism among smartphone applications. When the application detected a connection to NerveNet base station, the application start synchronizing its own database to the base station's distributed database. Base station's distributed database is maintained by user ID, group ID, application ID, and timestamp. So the application can only synchronize the data that have the same application ID. If several smartphone application have permit to synchronize certain group ID, the same data is synchronized among these smartphone applications through the base station's database. By using this application database synchronization scheme, the application developer can easily develop information sharing applications. The base station also maintained smartphone's connection status. Combining this status information, group-messaging application can be easily developed without using certain server system on Internet. Users don't aware of the database synchronization because all database synchronization is operated in background. In addition, user data access is only made to local database inside the smartphone, so user can send/read message at anytime even it he/she is out of communication range.

VI. NerveNet system and application demonstration at disaster drill in Onagawa town

We have cooperated with Onagawa town, Miyagi Prefecture, Japan, where is attacked by big tsunami up to 15m heights or more at the great east japan earthquake, march 11, 2011. Onagawa town location is shown in Fig.4. 55.9% evacuee died or still missing by this tsunami. Onagawa town office also hit by tsunami, and some people who went out office to check tsunami arrival after the earthquake never returned. To monitor the arrival of tsunami information remotely, or to correct and share the disaster information speedy, we installed four base stations and one IP video camera in Onagawa town. The network topology and installation location are shown in Fig.5. NerveNet base stations are connected with Wi-Fi based point-to-point communication system. Also Wi-Fi access point service is operated near base stations, so user around the base station can access to the network via Wi-Fi. High resolution IP zoom video camera system is installed in medical center to monitor sea level at any time from the town office. The video streaming image monitored from local town office is shown in Fig.6. By this system, the town officer can alert the tsunami arrival without approaching to the seashore. In addition, this IP camera is installed high location to be able to oversee whole town, so other disaster situation such as flood, the disaster situation can be quickly and easily grasped by controlling this camera. Fig.7 shows the camera image when a flood happened in Onagawa town. We have developed extension telephone application using NerveNet application service platform, and tried to use the disaster drill held in Miyagi prefecture on November 12, 2014. In this disaster drill, it is assumed that magnitude 8 level big earthquakes occurred near the sea of Miyagi prefecture, all mobile communication system was out of service at that time. Onagawa town officer correct damaged assessment information from the branch office by using extension phone application, and at the same time, they monitor the sea level in preparation for the tsunami arrival using IP video camera system. By this disaster drill, all system works well, and extension telephone application can be operated between library and town office without using Internet or other specific server system.

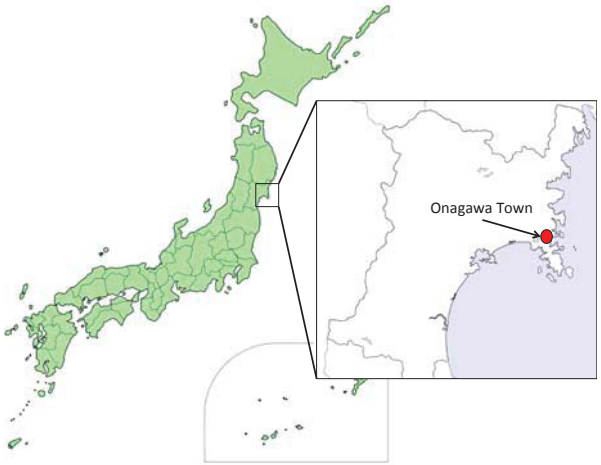

Fig. 4. Location of Onagawa town

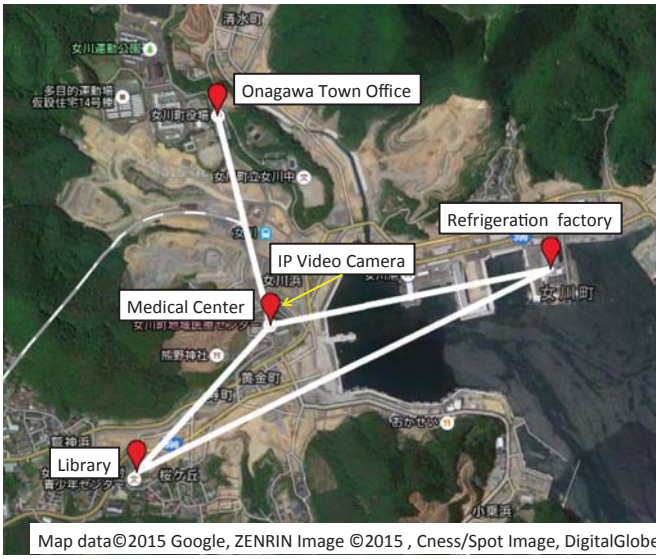

Fig. 5. NerveNet installation point and network overview

VII. Conclusion

In this paper, requirements for the communication system under disaster are organized, and NerveNet system platform and functions with original applications are introduced. Four NerveNet base stations with IP zoom video camera system are installed in Onagawa town as a pilot project for resilient regional self-managed network. NerveNet system, extension telephone application and IP camera surveillance system are used in a disaster drill, and these systems are well operated by Onagawa town officers. Utilizing these findings obtained from this trial, we are going to enhance NerveNet system to more robust, easy to user, easy to operate in future.

Acknowredgement

We would like to express the deepest appreciation to the Onagata town officers to cooperate with our pilot trials of NerveNet system.

***Abstract*— Spectrum occupancy rate (SOR) is one of the most important parameters for spectrum utilization measurement. This paper proposes a novel spectrum occupancy rate (SOR) measurement method based on CDF (Cumulative Probability Distribution Function) of received signal power, by using least square estimation of Gaussian noise period, to improve SOR measurement accuracy in low SNR conditions. Computer simulation confirms that SOR measurement accuracy is improved in low SNR conditions compared with the conventional threshold based SOR measurement method and simulation results of SOR measurement performance according to SNR of received signals, packet length, and number of measured samples are presented.**

Keywords- cognitive radio , cumulative probability distribution function , least square estimation , spectrum occupancy rate , Gaussian noise

I. INTRODUCTION

As mobile traffic in cellular networks and wireless LAN is rapidly increasing in recent years triggered by wide rollout of smart phone and tablet PC, demand for frequency spectrum has been dramatically increasing. However, frequency bands below 6GHz suitable for mobile services are already allocated to various existing wireless services and no more spectrum is available for new wireless services without spectrum re-allocation. On one hand, it was reported that there exists "white space" which is allocated to primary users but spatially and/or temporally unused [1].

Cognitive radio has been drawing a great deal of attentions as a technique to make it possible secondary use of white space possible as far as no harmful interference is given to primary users. Some papers estimated available white space, however it is still a controversial issue how much white spectrum is available in terms of space and time for secondary use [2][3]. As packet based wireless systems are widely used nowadays, spectrum occupancy rate (SOR) is also an important metric to evaluate available white space in terms of time.

To the best knowledge of the authors, a standard method for SOR measurement has not been established so far. A conventional SOR measurement method measures received signal power of each frequency bin, and calculates the number of samples which have larger signal power than the pre-determined threshold relative to the noise power level. The ratio of the number of samples higher than the threshold over all samples is given as SOR, or duty cycle of designated frequency bin [4]. A problem of this threshold based method is false detection and miss detection in low SNR conditions. As well-known, setting the threshold is a trade-off issue, i.e. false detection probability increases if the threshold is too low and miss detection probability increases if the threshold is too high. Thus, the threshold based SOR measurement method cannot accurately measure SOR especially when SNR is low and a few techniques to improve SOR measurement accuracy in low SNR conditions were proposed [5][6].

In order to improve SOR measurement performance in low SNR conditions, this paper proposes a novel SOR measurement method based on CDF (Cumulative Probability Distribution Function) of received signal power employing least square estimation of Gaussian noise period. The proposed SOR measurement method assumes Gaussian distribution for noise and estimates the ratio of Gaussian noise time period which minimizes square error of probability between reference CDF of Gaussian noise and measured CDF of received signals. Then, SOR is obtained by subtracting the ratio of Gaussian noise time period from one. The proposed method needs reference CDF of Gaussian noise, but does not need threshold setting, thus it can improve SOR measurement performance in low SNR conditions, compared with the threshold based SOR measurement method. The rest of this paper is organized as follows: Chapter 2 describes the problem of the CDF based SOR measurement method using threshold. Chapter 3 describes principle of the proposed SOR measurement method using least square estimation of Gaussian noise period and Chapter 4 shows simulation results of SOR measurement performance of the proposed method. Finally, Chapter 5 concludes this paper.

II. PROBLEM OF CDF BASED SSOR MEASUREMENT METHOD UISNG THRESHOLD

A. Principle of CDF based SOR measurement method

Cumulative probability distribution function (CDF) of received signal power, x in dB is obtained by measuring a sufficient number of measured samples for each frequency bin. Using CDF of measured signal power, SOR can be obtained from the ratio of the time period of signal plus noise over all the

measurement time period. Supposing that probability density function (PDF) of thermal noise is $p_N(x)$, that of received signal plus noise is $p_S(x)$, and SOR is R at a frequency bin, PDF of received signal, $p_R(x)$ and its CDF, $P_R(x)$ are given as follows:

$$p_R(x) = Rp_S(x) + (1-R)\cdot p_N(x) \quad (1)$$

$$P_R(x) = \int_0^x p_R(y)dy \cdot \quad (2)$$

Fig.1 shows principle of CDF based SOR measurement method where CDF of $p_N(x)$ and $p_R(x)$, $P_N(x)$ and $P_R(x)$ are illustrated when SNR=20dB and R=0.5. As shown here, there is a floor at R and R can be obtained as the probability from the floor to 1. Assuming Gaussian distributed noise for $P_N(x)$, we define the threshold x_0 and $P_N(x\text{-}x_0)$ as a threshold CDF to obtain R by calculating the cross point of $P_R(x)$ and $P_N(x\text{-}x_0)$. Supposing the cross point of $P_R(x)$ and $P_N(x\text{-}x_0)$ is $(X, P_R(X))$, R is given by

$$R = 1 - P_R(X), \quad (3)$$

where $P_R(X) = P_N(X\text{-}x_0)$. $P_N(x)$ can be measured for each frequency bin before SOR measurement and stored as the threshold CDF. We assume that Gaussian noise is Gaussian distributed and CDF of $P_N(x)$ is not changed during the SOR measurement. As $P_N(x\text{-}x_0)$ is theoretically less than $P_N(x)$ for any x if x_0 is larger than 0 and number of measured samples is sufficiently large. Then, three cross points for $P_N(x\text{-}x_0)$ and $P_N(x)$ are obtained, i.e. $(X_1, 0)$, $(X_2, P_R(X_2))$ and $(X_3, 1)$ where $X_1<X_2<X_3$ and R is obtained by $1\text{-}P_R(X_2)$ according to the equation (3). Otherwise, there are only two cross points, i.e. $(X, 0)$ and $(X, 1)$ for R=0 and R=1. In this case, if median value of $P_R(X)$ is less than x_0, R=0 and if it is larger than x_0, R=1.

B. *Problem of CDF based SOR measurement method using threshold*

As described above, performance of the CDF based SOR measurement method using threshold is affected by the threshold, x_0. Fig. 2 shows simulation results of SOR error according to the threshold when SNR=20dB and duty cycle=50%. Threshold is defined as the signal power normalized by noise power. As shown here, measured SOR error increases if the threshold is less than 5dB. As it is desirable to set the threshold as low as possible for SOR measurement in low SNR conditions, threshold of 5 to 6dB seems reasonable to minimize SOR error according to Fig. 2.

The CDF based SOR measurement method using threshold is evaluated by computer simulations. Simulation model is shown in Fig. 3, where received signals are weighted by windowing function and FFT is carried out to detect signal power per frequency bin. Then, SOR is estimated after obtaining CDF of signal power per frequency bin. Major simulation parameters are shown in Table 1, where IEEE802.11n standard is employed and subcarrier spacing of OFDM signal is 312.5 kHz. Bandwidth of frequency bin is set to 1MHz to accommodate multiple subcarriers in the frequency bin. This figure, 1MHz is being used in the experiments to evaluate the SOR measurement performance by the proposed scheme. The experimental results will be reported in near future. Windowing period is 768 assuming sampling frequency of 80MHz and bandwidth of frequency bin is set at 1.05MHz,

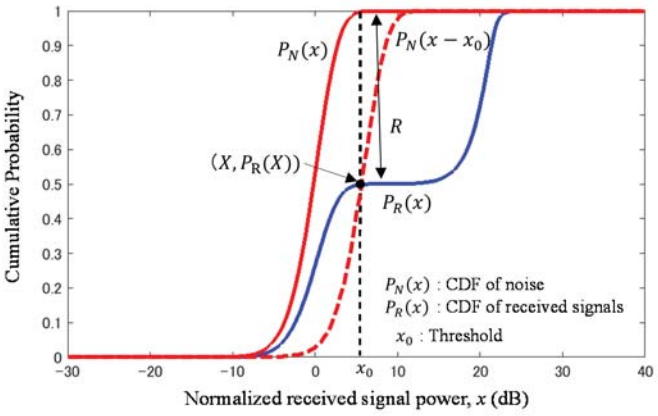

Fig.1. Principle of CDF based SOR measurement method using threshold.

Table 1. Major simulation parameters.

Number of subcarriers	56
OFDM symbol length	4 μs
Subcarrier spacing	312.5kHz
Modulation	QPSK
CP length	¼ OFDM symbol
Sampling frequency	80MHz
Windowing function	Hanning window, FFT length=768 samples
Frequency bin	1MHz

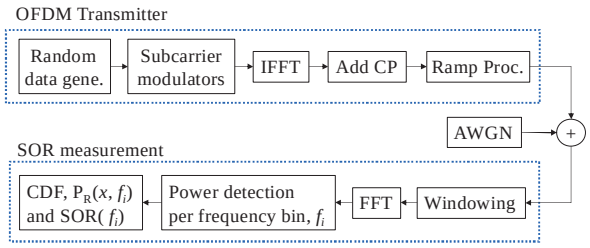

Fig.3. Simulation model for SOR measurement performance evaluation.

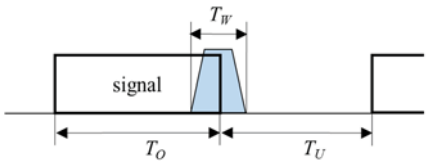

Fig. 4. Simulation scenario for SOR measurement performance evaluation.

which comprises 10 samples in frequency domain. Fig. 4 shows simulation scenario where an OFDM packet signal is transmitted periodically, where T_O is occupied time period of a packet signal, T_U is unoccupied time period or idle time period, and T_W is windowing time period. In this case, duty cycle is given by $T_O/(T_O+T_U)$.

Computer simulation has been conducted for performance evaluation of the CDF based SOR measurement method using threshold. Packet length is set at 256 OFDM symbols to avoid SOR error caused by time resolution, which is basically determined by windowing period, T_W and packet length, T_O as described later. Evaluated SOR error according to SNR is shown in Fig. 5, where threshold=6dB. As shown here, measured SOR is zero when SNR is less than 5dB, and measured SOR becomes lower than the actual duty cycle of 0.5 while SNR decreases to less than 10dB. In addition, smaller duty cycle results in more SOR error. This is because miss detection increases as SNR becomes low. However, the threshold cannot be further lower since measured SOR error increases due to false detection as shown in Fig. 2.

III. Principle of CDF based SOR measurement method using least square estimation of Gaussian noise period

A. Principle of the proposed SOR measurement method

As described in Chapter 2, SOR error of the threshold based method increases in low SNR conditions. In order to solve this problem, this paper proposes a CDF based SOR measurement method using least square estimation of Gaussian noise period.

Fig. 6 shows principle of the proposed SOR measurement method, where CDF of noise is $P_N(x)$ and that of received signal is $P_R(x)$. R is SOR to be measured from the received signals. We assume CDF of noise, $P_N(x)$ can be measured in advance and is not changed during SOR measurement, where x_1 is the minimum value, x_2 is the maximum value of the measured noise power, and 0dB is the mean value of the noise. If an appropriate range between x_{min} and x_{max} is chosen, we can assume that $P_R(x)$ is almost equal to $(1\text{-}R)P_N(x)$ since probability that signal plus noise is less than x_{max} will be sufficiently small when x_{max} is sufficiently low. With this assumption, the received signal is Gaussian noise and its CDF is $P_N(x)$ with probability of (1-R). Therefore, we can estimate R, i.e. spectrum occupancy rate which gives minimum error between $P_R(x)$ and $(1\text{-}R)P_N(x)$ within the range between x_{min} and x_{max}. As the least square error method is often used for evaluating the error, we define the square error, P_{SE} of $P_R(x)$ and $(1\text{-}R)P_N(x)$ as shown below:

$$P_{SE} = \frac{\int_{x_{min}}^{x_{max}} \{P_R(x) - (1-R)P_N(x)\}^2 dx}{x_{max} - x_{min}} \quad (4)$$

B. Optimization of estimation range, x_{min} and x_{max}

As P_{SE} is a function of x_{min} and x_{max}, it is necessary to determine, x_{min} and x_{max}. Supposing input signal is Gaussian noise only, x_1 is minimum and x_2 is maximum of measured noise power, we can assume $x_1 \le x_{min} < x_{max} \le x_2$. We optimize estimation range of x_{min} and x_{max}, which minimizes SOR error by computer simulations.

It is reasonable to set $x_{min}=x_1$ to increase number of samples for SOR estimation since larger number of samples becomes available. On the other hand, x_{max} should be as large as possible but it should not include probability of signal plus noise less than x_{max}. We introduce a parameter of noise period estimation factor, β for the proposed SOR measurement method. By using the parameter, β, x_{max} is given by

$$x_{max} = x_1 + \beta(x_2 - x_1), \quad (5)$$

where $0<\beta<1$. In a discrete system, P_{SE} is given by

$$P_{SE} = \frac{\sum_{i=N_{min}}^{N_{max}} \{P_R(x_i) - (1-R)P_N(x_i)\}^2}{N}, \quad (6)$$

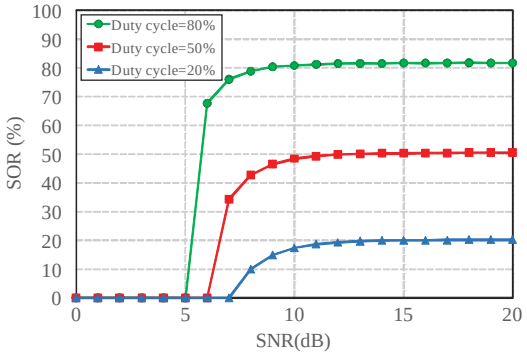

Fig.5. SOR error according to threshold.

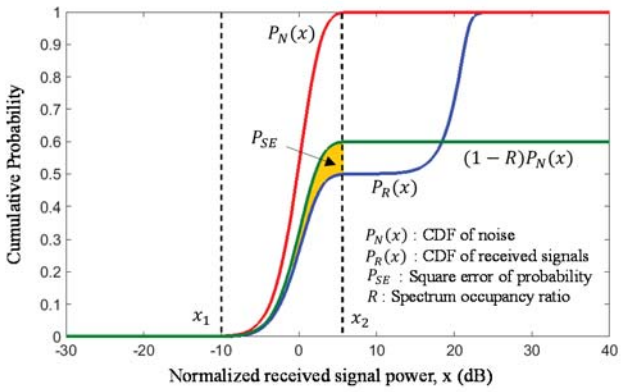

Fig. 6. Principle of the proposed SOR measurement method using least square estimation of Gaussian noise period.

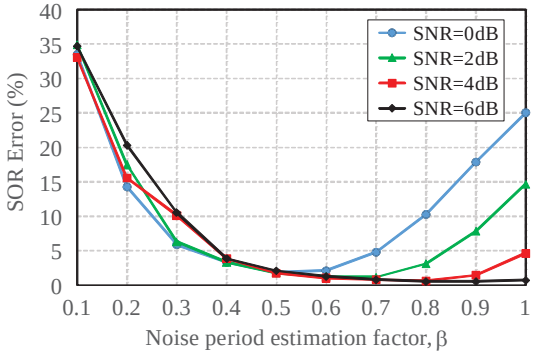

Fig. 7. SOR error as a function of noise period estimation factor, β.

where N_{min} corresponds to x_{min}, N_{max} corresponds to x_{max}, and N is total number of measured samples. Computer search has been conducted to determine β for SNR=0 to 6dB when duty cycle=50%. SOR error is evaluated for various β and SNR with the condition that P_{SE} is minimized.

Fig. 7 shows simulation results of SOR error as a function of noise period estimation factor, β. As shown here, optimal β for minimum SOR error becomes lower and SOR error increases gradually as SNR becomes lower. The results indicate that optimal β is changed according to SNR. Fig. 7 shows that β is as large as 0.9 to 1 and SOR error is be less than 1% when SNR=6dB. However, when SNR=0dB, optimal β is 0.5 to 0.6 and SOR error is 2 to 2.5%. As β=0.6 gives smaller SOR error than β=0.5 for SNR higher than 2dB, and SOR error difference is small between β=0.5 and β=0.6, β=0.6 is chosen as an optimal β in this paper. When β=0.6, almost half of Gaussian noise CDF is used for SOR estimation.

IV. Performance Evaluation of the Proposed SOR Measurement Method

A. Parameters related to SOR measurement performance

As expected from the principle of the proposed CDF based SOR measurement method, SOR measurement accuracy depends on various parameters such as bandwidth of frequency bin, windowing period, number of total measured samples, SNR of received signals, duty cycle, packet length and so on. Note that windowing period is closely related to bandwidth of frequency bin. Larger windowing period results in higher resolution in frequency domain but lower resolution in time domain. If bandwidth of frequency bin becomes smaller, detection of short packet becomes difficult. Therefore, the bandwidth of frequency bin, i.e. frequency resolution and time resolution is a trade-off issue.

Parameters shown in Table 1 are used for SOR measurement performance evaluation, and windowing period and bandwidth of frequency bin are fixed in the simulations. Then, SOR measurement performance according to packet length, SNR and total number of received samples is evaluated when duty cycle=80%, 50% and 20%.

OFDM signal is based on IEEE802.11n standard, and duty cycle of packet signal is given by $T_O/(T_O+T_U)$ as shown in Fig. 4. It should be noted that time resolution error is given by $2T_W/(T_O+T_U)$, because if a part of received packet signal is covered by windowing period, T_W, at either the head of packet or the tail of packet, or both of them, the period of $2T_W$ is regarded as occupied time when SNR is infinite. Therefore, measured SOR is given by $(T_O+2T_W)/(T_O+T_U)$ in the worst case. Note that packet length, T_O is fixed and T_U is changed according to the duty cycle of 80%, 50% and 20% in the simulation.

B. Impact of SNR

As the proposed method does not use the threshold, SOR measurement accuracy in low SNR conditions is expected to be improved. SOR measurement performance of the proposed method according to SNR is evaluated by computer simulations to confirm the validity of the proposed method and is compared

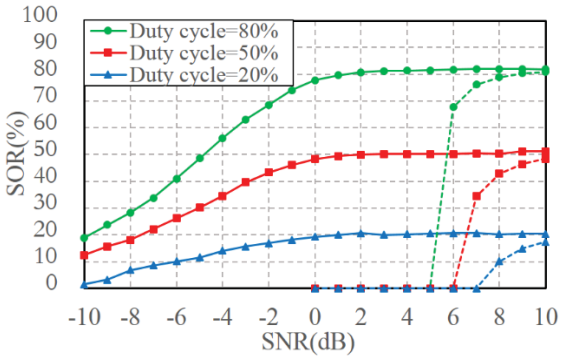

Fig.8. Simulated results of measured SOR according to SNR for duty cycle of 80%, 50% and 20% of proposed method and conventional threshold based method.

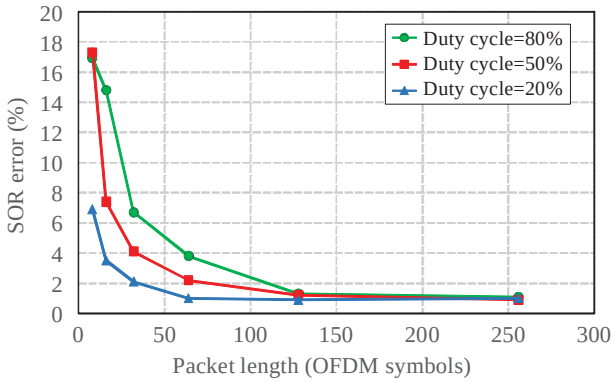

Fig.9. Simulated results of measured SOR according to packet length in OFDM symbols for duty cycle of 80%, 50% and 20% when SNR=5dB.

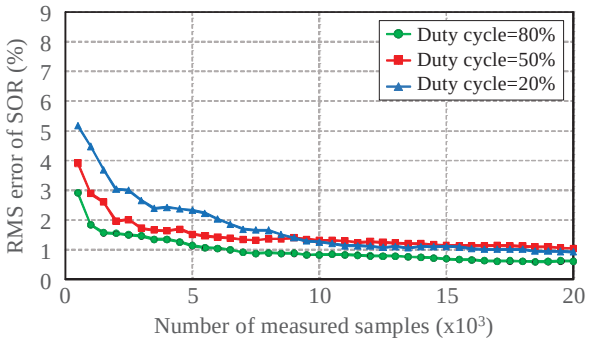
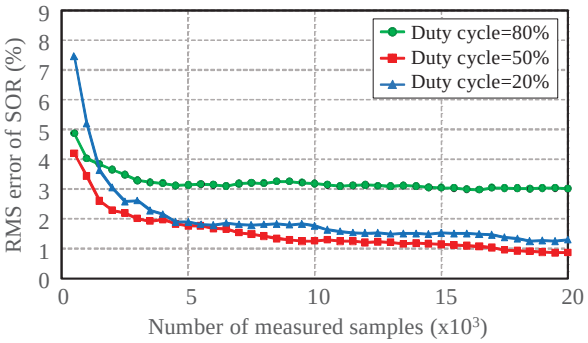


(1) SNR=5dB



(2) SNR=0dB

Fig.10. Simulated results of measured SOR according to number of measured samples for duty cycle of 80%, 50% and 20% when SNR=5dB and 0dB.

with that of the conventional threshold based method.

Fig. 8 shows simulation results of measured SOR according to SNR when duty cycle is 80%, 50% and 20%. Measured SOR of the proposed method is compared with that of the conventional method. Packet length is 256 OFDM symbols with 10500 samples, and SNR is -10dB to +10dB. As shown here, measured SOR of the conventional threshold method becomes zero when SNR=10 dB and duty cycle=20%. On the other hand, measured SOR is almost the same as actual duty cycle of 80%, 50% and 20% and SOR error is less than 1% when SNR=2dB or higher. Furthermore, the proposed method can measure SOR even if SNR is lower than 0dB though SOR error increases. This is significant improvement compared with the conventional threshold based method.

C. Impact of packet length

Packet length is also an important parameter to affect SOR measurement accuracy because of time resolution error given by $2T_W/(T_O+T_U)$ as described earlier, where T_W is windowing period, T_O is packet length and T_U is idle time period between packets. This equation indicates that SOR measurement error increases as packet length becomes shorter. SOR measurement error for packet length of 8, 16, 32, 64, 128 and 256 OFDM symbols is evaluated by computer simulations, where duty cycle is 80%, 50% and 20%, SNR is 5dB and number of measured samples is 10500. Simulation results of SOR measurement error as a function of packet length are shown in Fig. 9. As expected from theoretical time resolution error given by $2T_W/(T_O+T_U)$, the decrease of T_O results in increase of SOR error. In addition, as duty cycle increases, SOR error increases. As T_O is constant and T_U is changed to set the duty cycle, smaller duty cycle is given by shorter T_U, which causes the increase of SOR error. SOR error less than 2% can be achieved if packet length is longer than 128 OFDM symbols.

D. Impact of number of measured samples

As the proposed method uses CDF to estimate SOR, it needs sufficient number of measured samples, especially when duty cycle is large. This means that SOR measurement error is expected to decrease as number of measured samples increases. Computer simulations have been conducted to evaluate SOR error according to the number of measured samples, where packet length is 256 OFDM symbols and duty cycle is 80%, 50% and 20%.

Fig. 10 shows simulation results of SOR error according to the number of measured samples in the case of (1) SNR=5dB and (2) SNR=0dB. As expected, SOR error decreases as the number of measured samples increases. When SNR=5dB, SOR error is 2% or less when the number of measured samples is about $5X10^3$ for duty cycle of 80% and 50%. The number of measured samples needs to be slightly larger than $5X10^3$ to achieve SOR error less than 2% for duty cycle of 20%. However, we can conclude no significant SOR measurement error is observed as far as the number of measured samples is larger than $5X10^3$ when SNR=5dB. On the other hand, in the case of SNR=0dB, SOR error of about 2% can be achieved when the number of measured samples is about $5X10^3$ for duty cycle of 50% and 20%. However, SOR error does not decrease less than 3% by increasing the number of measured samples when duty cycle=80%. This SOR error floor seems to be caused by small number of samples for P_{SE} estimation to obtain R. When duty cycle is 80% and β=0.6, only 12% of all measured samples is used for P_{SE} estimation and relatively large number of measured samples less than x_{max} during the packet signal period are counted as noise when SNR is 0dB.

V. Conclusion

This paper proposed a novel CDF based SOR measurement method using least square estimation of Gaussian noise period, to improve SOR measurement performance in low SNR conditions. The proposed method estimates SOR, R which minimizes the square error between Gaussian noise CDF and noise part of the received signal CDF. Computer simulation results have confirmed that the proposed method can improve SOR measurement performance and achieve SOR error less than 2% when SNR is up to 2dB, by optimizing the estimation range, β. Furthermore, impact of SNR, packet length and number of measured samples on SOR measurement performance has been evaluated by computer simulations and simulation results have revealed how much SOR error is resulted by SNR, packet length and number of measured samples.

The remained work is to confirm the validity of the proposed SOR measurement method by experiments. Furthermore, SOR measurement performance of the proposed method needs to be evaluated in fading environments and it needs to be further improved in lower SNR conditions.

***Abstract*—To provide sustainable digital agro-advisory services to farmers, seamless flow of information from the farmers to the experts/expert systems, and vice versa is required. The query generated by the farmers, which may contain multimedia data regarding disease or pest attack in the crops is required to be transmitted to the experts for analysis. Further, after analyzing the query, an alert or advice from the expert system is required to be communicated back to the farmers within a tolerable delay. However in a country like India, network connectivity is extremely poor in several agricultural regions which makes the end-to-end connectivity between the farmers and the expert system intermittent. Therefore, providing agro-advisory services to farmers in a reasonable time becomes a challenge. In this paper, we propose a Delay Tolerant Network (DTN) based relay application model which enables agro-advisory services to farmers located in *No-network* or *Poor-network* zones. In the proposed model, end-to-end communication has been enabled with the help of Device to Device (D2D) communication and by introducing mobile relay nodes which can carry the queries (responses), from (to) the poor or no network zones to (from) the zones where communication is possible. Implementation of this model has been presented for the tea farmers of West Bengal and Assam, which can be extended for other applications in future.**

I. Introduction

In India, cellular network connectivity is very poor in several villages. Due to this, it has been observed that rural and tribal folks travel for several kilometers to make a voice call. Data connectivity of 2G/3G is even worse than the voice connectivity. From our extensive involvement in *Digital Farming* initiatives [1], the communication barrier due to the poor cellular network connectivity has been felt in several deployment locations. For instance, in remotely located tea farms and tea estates of Assam, telecommunication network is intermittent and very poor. Further, in the Araku constituency of Andhra Pradesh, which is known for its organic cultivation of coffee, rubber and spices, network is only available in selected pockets. Due to this, farmers of these regions face difficulty to get the relevant advice on their cultivation queries.

In the recent past, we have seen increasing applications of the Human Participatory Sensing in urban scenarios [2]–[4] such as traffic control, disaster information flow, epidemic monitoring, etc. In that direction, we have proposed a Rural Participatory Sensing (*RuralSense*) framework for agricultural applications [5] and have deployed the same for tea crop in West Bengal and Assam. A RuralSense mobile application has been provided to small and marginal tea growers of these areas in order to facilitate them to report various geo-tagged events from their farms. In addition, access to the web-based dashboard has also been provided to the experts to analyze the reported events and to advise back to the farmers. These events serve multiple purposes such as (a) asking queries, (b) digitization of the farm diaries, (c) self certification or tracing of the chemical applications and (d) generating contextual data for developing pest/disease/ yield/ water models for the cultivated crops. Fig. 1 illustrates a model digital farming platform; dotted lines indicate physical communication between the farmers and the expert system either through cellular or any other communication mode. The continuous lines indicate the logical flow of messages between the sensors placed in the farm and the expert system. This framework warrants a good communication network, which is the main focus of this paper. To overcome the limitations of poor network connectivity, we propose a novel Delay Tolerant Network (DTN) approach for agriculture applications. Note that throughout this paper we have used query and event interchangeably.

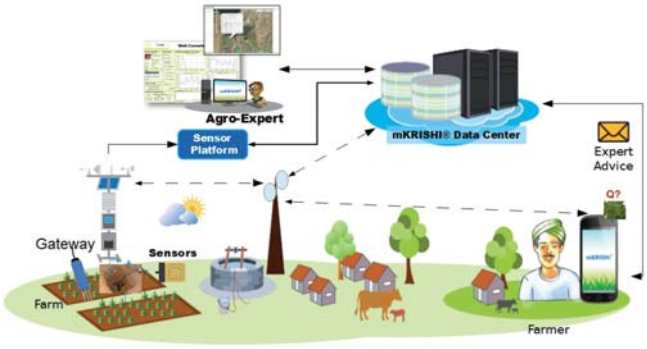

Fig. 1. Digital Farming Platform

Delay Tolerant Networks [6] has gained interest of many researchers in the last decade. It is designed for harsh and challenging conditions where continuous Internet connectivity can not be guaranteed. To compensate data loss due to frequent disconnections, a relay or DTN is required to store data packets for long time periods until connection to a forwarding node is established again. The use of this paradigm becomes critical in challenging scenarios like satellite, military, and rural applications. In countries like India DTN can be used as an alternative to provide seamless end-to-end connectivity.

In this paper, we have introduced a novel DTN-based agro-advisory framework to farmers working in a remote location with limited network connectivity. Using this we have proposed a mobile relay-based architecture which can be deployed in remote villages and provide expert advice to farmers' queries in a time bound manner. We have also provided an Android-based deployment framework to realize this. The rest of the paper is organized as follows. In Section II, we analyze the related work and in Section III, we explain the problem and our approach towards a practical solution. We then discuss the deployment framework in Section IV, and conclude this paper in Section V.

II. Related Works

Participatory Sensing [2], [3] has gained tremendous growth in the recent past and has created various innovative applications using crowd-sensing and crowd-sourcing technologies. In these technologies, huge data from the crowd workers is generated and processed for appropriate actions. We have explored crowd-sensing in our previous work on Rural Participatory Sensing [5] and Distributed Crowd Sourcing [7]. In [5], events are captured and reported with the help of a mobile application while in [7], tasks are assigned to the farmers to diagnose the plant diseases and pest classification. It is believed that for rural applications, crowd assisted sensing is an important source of data generation and the analytics performed on this big data shall serve the society for the years to come.

DTN was initially intended for Inter Planetary Networks (IPNs) [8] with a low network dynamic of satellites and rovers. In the DTN paradigm, communications can be intermittent and hence the nodes need to store the data till connection to a forwarding node is available again. By doing this, data communication can be guaranteed, even though the delay is substantial. In mobile wireless networks, the applications of DTNs have been envisioned for Vehicular Ad-hoc NETworks (VANETs) [9], Under Water Networks (UWNs) [10], Pocket Switched Networks (PSNs) [11], and suburb networks for developing regions [12], etc.

To provide Internet connectivity in rural India a Sustainable Access in Rural India (SARI) program [8], a DTN like framework has been initiated in which Internet kiosks have been distributed in different villages. However, providing and maintaining kiosks in every village is not feasible. Therefore, another project called Computers on Wheels (COW) [13] was started in 2006, in which motorcycles with Internet equipment act as mobile kiosks and travel to remote villages to collect the data from users. In this paper, we explore the feasibility of the DTNs in enabling value added services to the rural farmers in a time bound manner. We use the smartphones/mobiles with the mKRISHI® application instead of kiosks and provide DTN-based end-to-end connectivity to the farmers.

III. Problem Statement and Solution Approach

Time-bound agro-advisory services to farmers located in a remote area with either no or limited network connectivity is the challenge considered in this paper. The key goal of this paper is to remove the communication barriers due to unavailability of cellular networks.

In one of our endeavors on Rural Participatory Sensing (RuralSense) framework, farmers can collect (sense) various farming related information such as disease, pest, nutrient disorder and other activities. mKRISHI® is a Personalized Services Delivery Platform that enables two-way information exchange between farmers and expert systems that include virtual knowledge banks, Agriculture Experts and Procurement Officers (PO), etc. At the farmers' end, it uses participatory sensing (RuralSense) to collect and digitize the field data and mobile-based framework for the data communication. Each event/query generated at the farmers' end may consist of geo-tagged photographs, voice clip, meta-data, etc., and has a unique pair of Event ID (EID) bounded with the User ID (UID) which is assigned from the server. Moreover, it uses an application which can store the captured events/query in the local memory for communication at a later point of time.

At the expert system's end, it uses analytic tools and expert advisory services to evaluate the sensed data obtained from the farmers before communicating actionable advice to the farmers. This enables digitization of the farm and the farming related events. Note that, the availability of this information is extremely critical for decision makers in responding to the farmers' queries, in routing their agriculture inputs to the right location and at the right time. In poor network zones, farmers are however finding it difficult to have a seamless communication of the information. Therefore, a solution is desired which can be deployed in the mKRISHI® [1] framework such that seamless time-bounded communication can be realized. Moreover, the new solution should be easily integratable with the existing mKRISHI® framework. It should also be easy to use for the farmers.

A. Our Solution - a DTN Approach

In this section, we propose a novel solution which can be included in the mKRISHI® framework without much changes at the end points. The aim here is to provide network connectivity to the farmers in an alternative way. To realize this, we propose to use relay-based communication which can operate on the principle of DTN; an opportunistic mode that becomes critical in challenging scenarios like satellite and rural communications in emerging countries like India or Africa, where the lack of an infrastructure makes regular data communications almost impossible. DTN communications are thus the natural choice for a networking paradigm where nodes can be disconnected from the regular network for the majority of the time and exchange of data can take long time. To provide DTN-based solution, we propose a new entity into the mKRISHI® framework called *Relay Node*. A relay node can be any other smartphone which can be used by other fellow farmers, farm agents, or field executives, that comes in close proximity to the farmers at the remote locations and has the following capabilities: (i) collect the farmers' sensed data or queries using Device to Device (D2D) services [14], (ii) transmit the collected queries from one or more farmers to

the expert system using available network technologies (Wireless Fidelity - WiFi, cellular or any other) in a time-bound manner, (iii) collect and communicate the acknowledgement (ACK) and advisories from the expert system to the farmers. Fig. 2 illustrates the possible modes where multi-hop relay communication can be introduced to eliminate the network connectivity problem at the farmers' end.

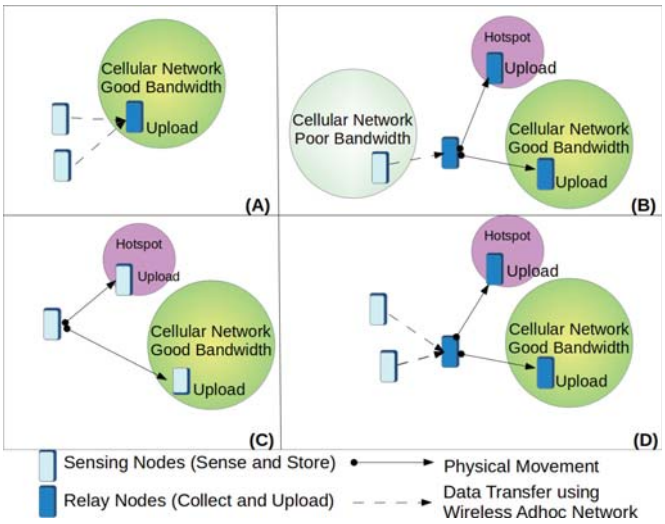

Fig. 2. Problem Cases - Need for DTN: (A) No network farmer zone, Relay with network, (B) Poor network farmer zone, Relay movement to a network zone, (C) No network farmer zone, farmer movement to a network zone, (D) No network farmer zone, Relay movement to a network zone

B. Building Blocks of our Solution

Various modules related to our architecture and the communication possibilities are explained through Fig. 3. Basic building blocks of our solution are as follows:

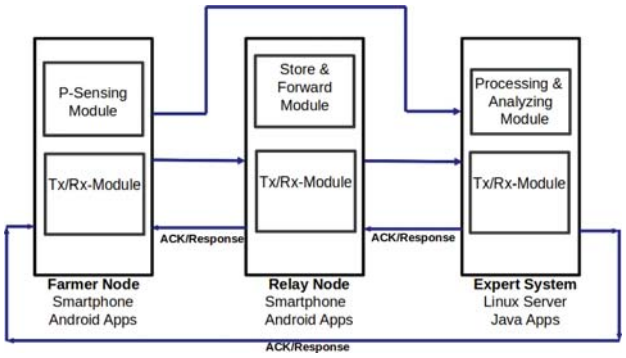

Fig. 3. Building Blocks - DTN-based Architecture

Farmer Node: In the present setup of the mKRISHI® framework, farmer node is an Android Application (App) targeted for users with Android devices having OS version not less than 3.0 and basic configurations like camera, Global Positioning System (GPS) and WiFi. The application empowers the users of remote locations to send ground scenarios in the form of 'events' that fundamentally consists of an image of the situation or surrounding, predefined textual labels and/or a voice clip. In cases where a particular farmer has a basic mobile phone instead of smartphone, he can still use any other farmer's smartphone with his own authentication to upload his queries. In this case, two different identities are assigned to the farmer - (i) physical identity, i.e., his own phone number, and (ii) logical identity, which is the phone number of the smartphone he/she uses for log-in. These events are required to be uploaded to the server over the Internet so that users can receive advices or suggestions. The application allows users to store these events, for later submission, in case of poor or no network connectivity. While uploading, the system follows DTN approach to relay the data to an agent or relay node.

Relay Node: It employs the aforementioned farmer node Android App with an additional privilege of aggregating queries from farmer nodes which are incapable of uploading events. The relay node is required to press a button in the application to create a WiFi Protected Access 2 (WPA2) secured WiFi Hotspot in the region. A limited set of farmer nodes (based on device hardware), simultaneously, could connect to the relay node and send their events to it. The relay node would then upload all the events to the server either through moving physically to a cellular network zone or connecting to the Internet through other means. The relay node can also carry the acknowledgements and the responses meant for the users provided by the expert system.

Server or Expert System: It is is a Linux powered, 16 core Xeon processor rack with 32GB RAM, hosted in a virtualized environment and capable of handling huge loads by applying standard techniques of distributed computing. It hosts the mKRISHI® server application which handles the 'events' coming from remote locations. The application is designed to maintain data integrity and has the capacity to send instant acknowledgements to the farmer nodes.

Communication between the Farmer node and the Relay node is realized through low powered ad-hoc D2D communication [14], such as WiFi Direct, WiFi Hotspot and Bluetooth, etc. It uses the licence free spectrum (ISM band) and self-initiated discovery and signalling techniques for the D2D communication initialization. At present, it uses a very low power (fixed) for the D2D communication; transmission power can be further reduced using sophisticated signalling techniques.

IV. Deployment and Evaluation

To evaluate our proposed architecture, we have extended the mKRISHI® framework with DTN functionalities. The system model is implemented to work seamlessly under all communication scenarios. The details of our implementation framework is explained as follows:

A. Scanning of Access Networks

This module is implemented in the farmer node as well as in the relay node using Android App. Once the event is sensed, the farmer node creates a message (query) and scans for an access network to communicate the same to the central expert system. The communication can be direct through the cellular network or indirect through the mobile relay node.

B. Communication Modes

Based on the availability of access networks we have implemented two modes for access network selection and communication. Mode-1 belongs to direct communication whereas Mode-2 is Relay-based communication. In this paper we focus on Mode-2 communication only.

- *Mode-1(a) - Direct:* When the Cellular or any other connectivity is available at the farmers' end, it can directly transmit the query to the central expert system.
- *Mode-1(b) Direct Periodic (P-Direct):* Under this mode, the application at the farmers' end periodically scans the signal strength of the cellular network. Upon getting good connectivity, it can transmit the query through the available cellular network. This can be applicable in scenarios where the connectivity varies between good and bad within time periods in minutes.
- *Mode-2 Periodic DTN:* This is the scenarios where the connectivity varies within time periods of hours. In such situations, if the channel is bad then most likely it will remain same for a long time. Therefore, for such situations a relay agent with a DTN enabled relaying application module will visit the farmer place and collect farmers' queries to its own device and then relay the collected queries to the server. The relay node can also collect the ACK/responses for the queries from the server and deliver to the farmer nodes through this communication mode. In this mode, the query won't be deleted from the farmer node till an ACK/response is received from the server. In case of no ACK/response received from either the server (directly) or through the relay node within a pre-defined time frame, the farmer node will restart the access scanning process for re-transmission.

C. Relay Node Communication

For query collection from the farmer nodes, the relay node creates a WPA2 secured WiFi Hotspot in the region. Farmer nodes can register with this WiFi Hotspot and send their queries to the relay node. Once registered, the farmer's authentication details are saved in the relay node and need not to register again with the same relay node. In this way, secure D2D communication is realized between the farmer and the relay node. The relay node would then transmit all the queries to the server using its own network or by physically moving to a available network zone. Multi-hop relaying is also possible but currently out of the scope of this paper. Similar to the forward direction flow of queries, the relay node can also collect the ACK/responses for the queries from the server and deliver to the farmer nodes within a permissible time bound.

D. Reverse flow of ACK/Response

The ACK/response can be sent directly to the farmers using Short Message Services (SMS) or Hyper Text Transfer Protocol (HTTP) based messaging. In case of non-availability of network ACK/response can also be sent through designated relay nodes. In case of the query came from a farmer who has two identifications as physical and logical, the ACK/Responses will be routed to the logical identity only and it is the job of the farmer to logging into the smartphone and retrieve its message. The forward and reverse flow of message between the farmer node and the server can also happen using different relay nodes. To enable this multiple relay node options, the server maintains a map of relay nodes and their registered farmer nodes. Note that, Responses are required to be received by the farmer within a specified time period (T_r) starting from the query generation time (24-hour in this paper). Else, the farmer node discards the query; new queries can be generated again. Similar to the Responses, the ACKs are also to be received by the farmer node within a smaller time period T_d ($T_d << T_r$). It is generally assumed that relay node can go online fairly quickly ($< T_d$) since it is mobile. To take care of the situation that the relay node due to some exigency is unable to connect to the server within this time period, we are having a timeout and a re-transmission to a possibly different relay node to ensure reliable message delivery to the server.

We now explain the control flow of all the events required for the end-to-end communication between the farmer node and the server. Fig. 4 illustrates the different phases and modes of the communications. Under Mode-1 communication queries can be sent directly to the server node and ACKs/Responses can be delivered to the farmer node directly. Upon receiving the ACK the query associated with the event is deleted from the farmer node. In Mode-2, two cases are possible. In the first case, i.e., when the relay node is on-line, both the query as well as the ACK/Response can be received before the expiry of the desired time; event can be deleted after the ACK is received at the Farmer node. Note that, the ACKs/responses can also be received directly using SMS. In the second possible case, i.e., when the relay node is off-line, even after collecting the queries, the relay node may not be able to transmit the queries to the server immediately due to network issues. In this case, the relay node needs to physically move to a network zone to transmit the queries. This can lead to delay in receiving the ACK/response. Hence timeout can occur at the farmer node resulting in retransmission of the queries (and possible deletion of the query). Note that, retransmission of the farmer queries can be made through another relay node; multiple retransmission attempts can be made till the Response timeout.

E. Proposed DTN-based Server Application

As discussed before, Android Apps are being designed for the farmer and relay nodes. Appropriate Java-based applications are also designed at the server end. These applications provide necessary platforms to visualize the queries, analyze them and communicate back responses or general information (advices/alerts) to the selected farmers (unicast or multicast). An SMS Gateway has been interfaced with the server in order facilitate the communication of ACKs, alerts, or responses in the form of the SMSs.

Fig. 5 shows the screen-shots of the Android Apps designed and implemented on the Farmer and the Relay nodes. These are simple and easy to use applications, which can be used by the farmers without much difficulty. Local language support is

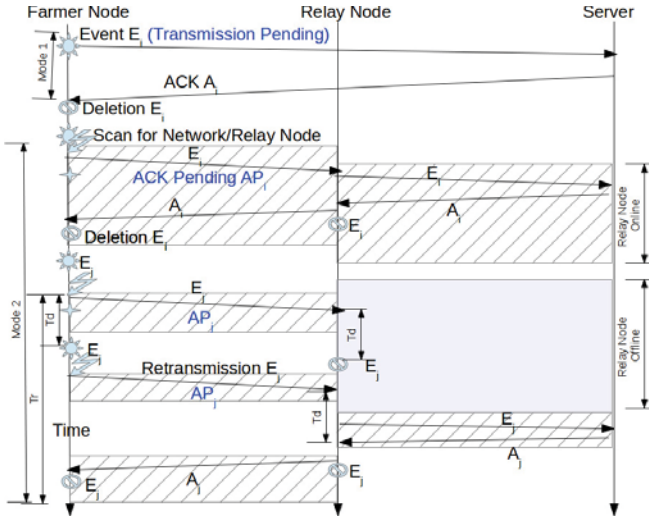

Fig. 4. Timing Diagram - DTN-based Solution

also being provided in the Apps, such that they can be adapted easily. Appropriate care has been taken by keeping security and privacy settings of smartphones intact while installing these Apps.

Fig. 5. Android-based Deployment

F. Practical Deployment

At present laboratory prototypes are tested for (i) end-to-end data communication, (ii) ACK delivery through SMSs and through data communications, (iii) event creation, deletion, transmission and re-transmission, (iv) effect of D2D communication on interference and it's impact on throughput, (v) scalability test for the maximum number of Farmer nodes one Relay node can support, (vi) privacy and security threats which can result out of the relay-based communication, etc. Post laboratory tests, practical deployment will be considered in the Tea gardens of Assam followed by other areas in the North-East, Andhra Pradesh and Maharashtra.

V. Conclusions

In this paper, we have observed the need of a delay tolerant framework for the remote farmers with poor network connectivity and have proposed a novel DTN-based architecture for end-to-end communication. In our model, mobile relay node visits the poor channel farmers, collects their queries and transmits to the server. In future, we plan to work on estimation of the relay node's availability at a certain location. This can help us to trigger other participatory sensing applications and can also be used to initiate the sensing operation just before the relay nodes are expected to arrive in communication range of the farmer nodes. We believe that our proposed model is first of its kind to be implemented which can benefit the farming community to a large extent and can provide Digitization of the Agriculture domain in India.

***Abstract*— Lately, multi-hop networks which transmit data packets through some relay nodes have received much attention. We focused on the fact that the total power consumption of the whole network in multi-hop communications consists of the transmitted power and the consumed power. Our goal is to theoretically show the effectiveness of multi-hop communications in terms of total power consumption. First, we theoretically derived a closed form expression for the total power consumption in certain linear multi-hop networks. Next, we showed the validity of the derived expression using theoretical analyses and computer simulations. Moreover, we considered the predominance of multi-hop communications compared to direct communication, by theoretically examining the maximum and optimum number of hops and showing numerical examples.**

Keywords*— *Multi-hop Communications; Transmitted Power; Energy Consumption; Total Consumed Power; Theoretical Expression

I. INTRODUCTION

Recently, multi-hop networks without a fixed infrastructure, which transmit the data packets through some relay nodes, have received much attention [1],[2]. The merits of multi-hop networks are that the total transmission power decreases and the space use efficiency of radio resources improves. On the other hand, a demerit of multi-hop communications is that the end-to-end delay due to overhead by relaying is large, so time use efficiency falls. So far, theoretical approaches for linear multi-hop networks have been studied [3]-[9]. In [3], [4], maximum throughput analyses for IEEE802.11 DCF protocol multi-hop networks are shown. In [5]-[6], analyses of the optimum number of hops under various conditions are shown. In [5], analyses using coded TDMA multi-hop transmission are shown. In [6], analyses using Hybrid Automatic Repeat reQuest (HARQ) protocols in a quasi-static fading environment are shown. Also, focusing on the power consumption of relay nodes in a sensor network, the impact of some physical layer parameters on power consumption in relay nodes [8] and modeling of the relationship between the transmitted power and power consumption in relay nodes [9] are shown.

On the other hand, our research goal is as follows. A multi-hop network transmits data packets through some relay nodes. In the case of equidistant transmission, it can achieve lower transmission power than a single-hop network, because the transmission power decreases in inverse proportion to the square (or more) of the distance. It is generally known that the transmission power decreases as the number of relay nodes increases. On the other hand, the relay nodes also have their own power consumption that does not contribute to transmission. Therefore, the total power consumption, which is the transmission power of the relay nodes and their own power consumption, can be more than that of direct communications for some numbers of relay nodes and values of power consumption. So, we focus on the fact that the total power of the whole network consists of the transmitted power and the consumed power. Our goal is to theoretically show the effectiveness of multi-hop communications in terms of power consumption. In this paper, we theoretically derive a closed form expression for the total power consumption in linear multi-hop networks. Next, we show the validity of the derived expression using theoretical analyses and computer simulations and consider the predominance of multi-hop communications compared to direct (single-hop) communication. Moreover, we consider the maximum number of hops and optimal number of hops theoretically and show numerical values in areas which multi-hop communications are more predominant than direct communication. The rest of our paper is organized as follows. In section 2, we derive a closed form expression for the total power of the whole network. In section 3, we evaluate the derived theoretical performance using computer simulations. Finally, we present our conclusions in section 4.

II. CLOSED FORM EXPRESSION FOR LINEAR MULTI-HOP NETWORKS

A. Analysis Model and Assumed Conditions

Though wireless radio environment performance depends on a combination of the three phenomena: path loss, shadowing, and multi-path fading, we consider only path loss and shadowing for ease of analysis in this paper. We consider a multi-hop network whose n relay nodes are stationary and placed at equal intervals on a straight line between the transmitter and the receiver as shown in figure 1(a). Therefore, when the number of relay terminals is zero, it corresponds to direct communication (single-hop). As shown in figure 1(b), the data from the transmitter are transferred to the receiver via relay nodes. We assume the following two conditions in our analysis.

1. The path loss coefficient γ, the shadowing deviation σ and frequency band are equal among all relay nodes.
2. There is no delay in the relay nodes.

B. Derivation

The template is used to format your paper and style the text. All margins, column widths, line spaces, and text fonts are prescribed; please do not alter them. You may note peculiarities. For example, the head margin in this template measures proportionately more than is customary. This measurement and others are deliberate, using specifications that anticipate your paper as one part of the entire proceedings, and not as an independent document. Please do not revise any of the current designations.

(1) The transmitted power P_t

(A) Direct (Single-hop) communication

First, we derive the transmitted power for direct communication [10]. As the electromagnetic field strength monotonically decreases with the distance from the transmission point, the received power at a distance d, $P_r(d)$ can be expressed by (1) using the transmitted power P_t.

$$P_r(d) = P_t K\left(\frac{d_0}{d}\right)^{\gamma} \cdot \quad \text{..... (1)}$$

Here, γ is the path loss coefficient, d_0 is the reference distance and K is propagation loss at the distance d_0. The outage probability, $P_{out}(P_{r_min}, d)$, is the probability that $P_r(d)$, which is expressed by expression (1), is smaller than a threshold value, P_{r_min}. It is expressed by (2).

$$P_{out} = P(P_r(d) \le P_{r_\min}) \cdot \quad \text{..... (2)}$$

However, the value of P_{r_min} depends on the transmission environment and system. It can be expressed by (3) in both path loss and shadowing environments.

$$P_{out} = 1 - Q\left\{\frac{P_{r_\min} - P_r(d)}{\sigma}\right\} \cdot \quad \text{..... (3)}$$

Here, σ is the shadowing deviation. Also, the Q-function, $Q(z)$ is the probability of a Gaussian distributed random variable, X with a mean of 0 and a variance of 1. When X is larger than z, it is expressed by (4).

$$Q(z) = \int_z^{\infty} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{y^2}{2}\right) dy \quad \text{..... (4)}$$

Therefore, when inv_Q(z) is the inverse function of the Q-function, Q(z), the transmission power Pt which is necessary to send data to the terminal at the point at a distance d is expressed by (5).

$$P_t = P_{r_\min} K^{-1}\left(\frac{d}{d_0}\right)^{\gamma} 10^{-\left\{\frac{\sigma \times \text{inv_Q}(1 - P_{out})}{10}\right\}} \equiv P_{t_d}(d) \quad \text{... (5)}$$

(B) Multi-hop communications

As the number of times a signal is relayed from the transmitter node S to the receiver node D is n+1, the distance of one-hop, d_{hop} is expressed by (6).

$$d_{hop} = \frac{d}{n+1} \cdot \quad \text{..... (6)}$$

When the outage probability from the (k-1)-th node to the k-th node is $P_{out(k)}$ when k is larger than zero, P_{out_end} is the outage probability from the transmitter node S to the receiver node D. It is expressed by (7).

$$1 - P_{out_end} = \prod_{k=1}^{n+1}\left(1 - P_{out(k)}\right) \cdot \quad \text{..... (7)}$$

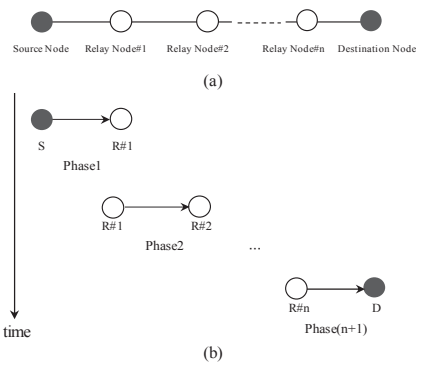

Figure 1 Linear Multi-hop Networks.

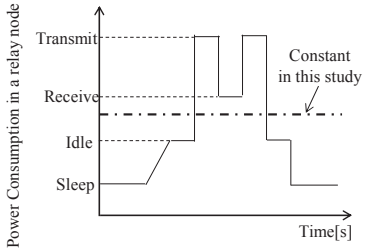

Figure 2 Power Consumption in a relay node, P_{node} [12].

If the value of the outage probability in each hops is equal, that is, $P_{out(1)}=\ldots=P_{out(n+1)}=P_{out_hop}$, (7) can be rewritten as (8).

$$1 - P_{out_end} = \left(1 - P_{out_hop}\right)^{n+1} \quad \text{..... (8)}$$

We can get (9) from (8).

$$P_{out_hop} = 1 - \sqrt[n+1]{1 - P_{out_end}} \cdot \quad \text{..... (9)}$$

By replacing P_{out} in (5) with P_{out_hop} in (9) and replacing d in (5) with d_{hop} in (6), the transmitted power per hop, P_{t_hop} is expressed by (10).

$$P_{t_hop} = P_{r_\min} K^{-1}\left(\frac{d}{(n+1)d_0}\right)^{\gamma} 10^{-\left\{\frac{\sigma \times \text{inv_Q}\left(1 - \sqrt[n+1]{1 - P_{out_end}}\right)}{10}\right\}} \quad \text{.(10)}$$

As the number of times a signal is relayed from the transmitter node S to the receiver node D is n+1, the transmitted power for the whole network, Pt is expressed by (11).

$$P_t = (n+1)P_{t_hop} = (n+1)P_{r_\min} K^{-1}\left(\frac{d}{(n+1)d_0}\right)^{\gamma} 10^{-\left\{\frac{\sigma \times \text{inv_Q}\left(1 - \sqrt[n+1]{1 - P_{out_end}}\right)}{10}\right\}} \equiv P_{t_m}(d, n)$$

.....(11)

Here, we substitute 0 for n in (11), which corresponds to (5) for direct communication. In other words, the following equat on is valid.

$$P_{t_d}(d) = P_{t_m}(d, 0) \cdot \quad \text{..... (12)}$$

Also, when we substitute 0[dB] for σ in (11), it corresponds to the case with only path loss[11].

(2) The power consumption P_{node}

In general, as shown in figure 2, the power consumption in relay nodes is changed temporally corresponding to the statu, such as idle, sleep, transmitted data and received data[12]. In [13], a mathematical analysis of power consumption in data transmission over IEEE802.11-based wireless multi-hop networks is shown. However, in this paper, we assume that

data is continuously transmitted from the source node to destination node with a constant level of power consumption in each relay node for ease of analysis.

(3) The total consumption P_{total}

The total power consumption is expressed by (13) using the transmitted power expressed by (11), the power consumption in a relay node, P_{node} and the number of relay nodes (n).

$$P_{total}(d,n) = i_{re} \cdot \{P_{t_m}(d,n) + n \cdot P_{node}\}, \quad n \geq 0 \cdot \cdots\cdots\cdots (13)$$

Here, when we substitute 0 for n, direct communication is done. When we substitute a number larger than 0 for n, multi-hop communication is done.

C. Discussion

In this section, we examine expression (13). In direct communications, the total power consumption consists of only the transmitted power in the source node S and it is constant regardless of the number of relay nodes. On the other hand, in the total power consumption in multi-hop communications, there is a trade-off between the first and second terms in (13). The former is the reduction in the transmitted power and the latter is the increase in the power consumption in relay nodes. Moreover, the latter depends on the power consumption in a relay node (P_{node}) and the number of relay nodes (n).

(A) Maximum hops h_{max}

In figure 3, we show the total power consumption as a function of hops. As shown in Fig.3, multi-hop communications is more predominant than direct communication in area-A. In area-A, we can see two areas, area-A1 which is more predominant for the first item in (13) and area-A2 which is more predominant for the second item in (13). From the point of view of total power consumption, the conditions which are more predominant for multi-hop communications than for direct communication are expressed by (14).

$$\begin{cases} P_total\ (\mathrm{d},\ \mathrm{h}) < P_total\ (\mathrm{d},\ 0) \\ 1 < h \end{cases} \cdots\cdots\cdots\cdots\cdots (14)$$

From (14), we can get the maximum hops h_{max} shown in figure 3.

(B) Optimum number of hops h_{opt}

In area-A, the number of hops which minimizes the total power consumption, h_{opt} exists. If P_{total} is considered to be continuous, the optimization condition is expressed by (15).

$$\frac{d}{dh}\{P_{total}(d,n)\}\Big|_{h=h_{opt}} = 0 \cdots\cdots\cdots\cdots\cdots\cdots (15)$$

III. Performance Evaluation

We show the validity of the derived expressions (11) and (13) using theoretical analyses and computer simulations. We used NS2 [14] as a network simulator. Moreover, we consider numerical values for expressions (14) and (15). We show our evaluation model in figure 1 and the basic simulation parameters [14] in table 1. We make the following two assumptions in our performance evaluations.

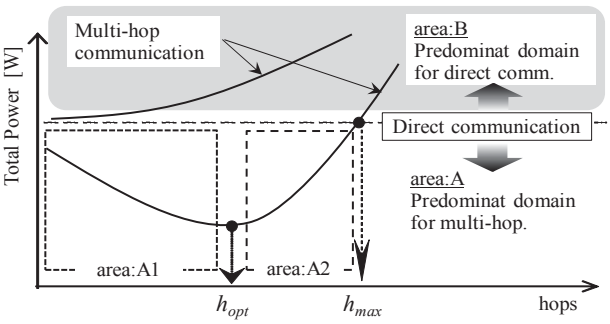

Figure 3 Analysis on total power consumption based on (13).

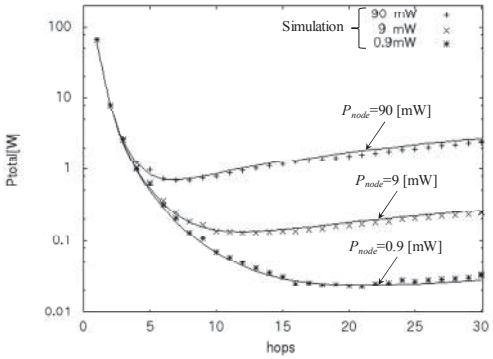

Figure 4 Relationship between number of hops and total power for some values of P_{node}. (Outage prorability P_{out}:3[%])

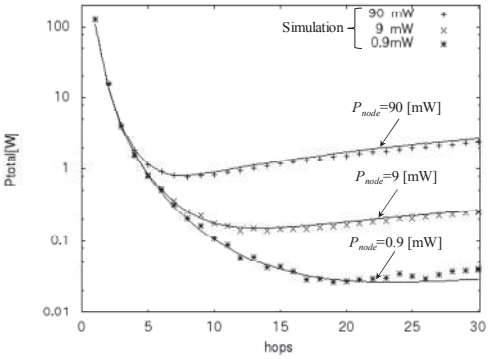

Figure 5 Relationship between number of hops and total power for some values of P_{node}. (Outage prorability P_{out}:1[%])

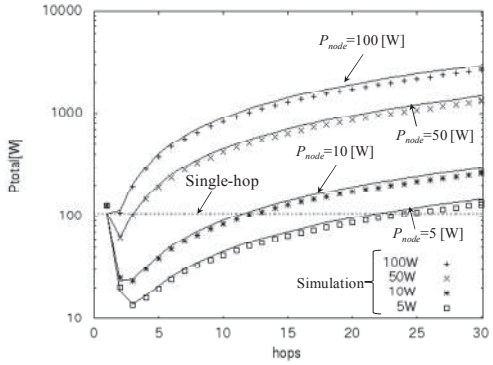

Figure 6 Relationship between number of hops and total power for some values of P_{node}. (Outage prorability P_{out}:1[%])

1. In (13), the average number of transmission times i_{re} is one, in other words, the data is sent without retransmission between relay nodes for simplification.
2. From the purpose of this study as mentioned in chapter 1, we do not consider power consumption in both the source node *S* and the destination node *D*.

A. When the number of the hops is changed and the distance between the transmitter and the receiver is fixed

We evaluate the performance for various values of outage probability, P_{out} and power consumption, P_{node}. In other words, we show the total power consumption as a function of hops. In figure 4, the result when P_{out} = 3% and in figure 5, the result when P_{out} = 1% are shown. From Fig.4 and Fig.5, as the theoretical value and simulation results are almost equal regardless of P_{out} and P_{node}, this shows the validity of the derived expression. However, when P_{node} is 0.9[mW] at P_{out} = 1%, some difference is seen between theoretical values and simulation results after about 25[hops]. In figure 6, the results for P_{node}=5, 10, 50, 100[w] are shown. As was the case for Fig.4 and Fig.5, from Fig.6, as the theoretical value and simulation results are almost equal regardless of P_{out} , P_{node}, this shows the validity of the derived expression. Here, in Fig.6, the performance of direct communication is shown using a short dashed line, and the value is 106[W] from expression (5).

(A) Maximum hops h_{max}

We verify the discussion mentioned in section 2. From Fig.6, in the case of P_{node} =5, 10, 50[W], an area in which multi-hop communications is more predominant than direct communication, area-A in Fig.3, exists. In particular, the maximum number of hops h_{max} mentioned in 2.3.1 are 21 hops (5[W]), 11 hops (10[W]), and 2 hops (50[W]). The reason is as follows. From (13), when the number of nodes *n*, i.e., hops, is larger, the value of the first term in (13) is smaller due to the effect of multi-hop communications. Therefore, if a smaller value of P_{node} is set for a fixed ~~the~~ number of nodes *n*, P_{total} can be kept smaller. As a result, the value of the maximum number of hops h_{max} is larger. On the other hand, if a larger value of P_{node} is set, the opposite can be said. Also, P_{total} is 114[W] at 2 hops when P_{node} is 100[W]. Therefore, we calculate the largest value of P_{node}, which satisfies (14) and show the result in figure 7. In Fig.7, when P_{node} is set to be more than 93[W], direct communication is more predominant than multi-hop communications.

(B) Optimum number of hops h_{opt}

If the area in which multi-hop communication is more predominant than direct communication, area-A in Fig.3, exists, the optimum number of hops h_{opt} mentioned in 2.3.2 exists. In particular, the h_{opt} are 2 hops (P_{node} = 50, 23[W]) and 3 hops (P_{node} = 14[W]). Then, the minimum values of the total

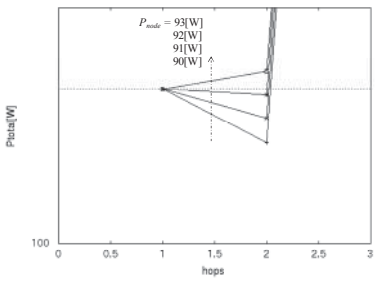

Figure 7 Relationship between number of hops and total power for some values of P_{node}. (Outage prorability P_{out}:1[%])

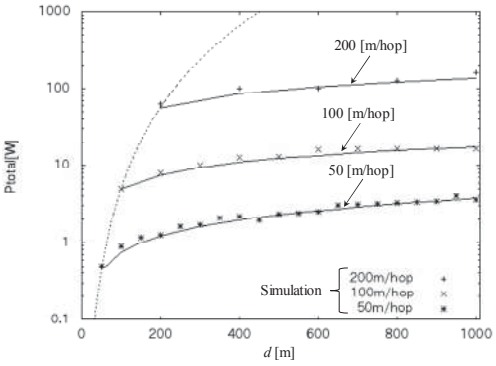

Figure 8 Relationship between distance and total power as a function of the distance per hop. (P_{node}:90[mW], P_{out}:3[%])

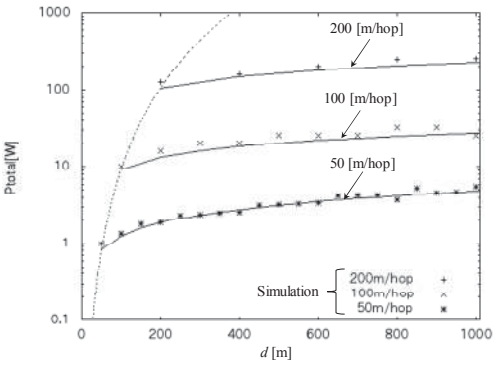

Figure 9 Relationship between distance and total power as a function of the distance per hop. (P_{node}:90[mW], P_{out}:1[%])

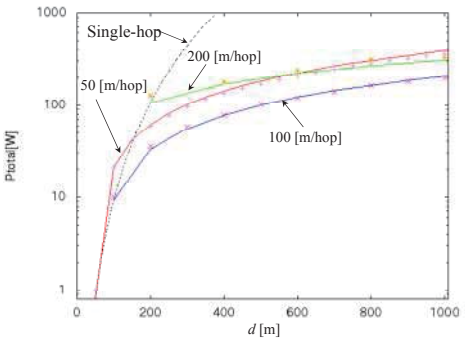

Figure 10 Relation between distance and total power for the distance per a hop. (P_{node}:20[W], P_{out}:1[%])

power consumption are 64[W], 23[W] and 14[W]. This is because if smaller values of n and P_{node} are used, we can get smaller values of P_{total}.

B. *Effect of changing the distance between the transmitter and the receiver with a fixed distance between relay nodes*

First, we evaluate the performance for P_{node}=90[mW]. In figure 8, the result for P_{out} = 3% and in figure 9, the result for P_{out} = 1% are shown. From Fig.8 and Fig.9, as the theoretical value and simulation results are almost equal regardless of P_{node} and d_{hop}, we show the validity of the derived expression. In both Fig.8 and Fig.9, we can see the following two points. Multi-hop communication is more predominant than direct communication regardless of d_{hop}. If the value of d_{hop} is larger, the total power consumption is larger regardless of the communication distance, d. Later, we consider the reasons for these results. Specifically, in Fig.9, the total power consumption P_{total} which is necessary to send data to a point at a distance d=600[m] is 3.5[W](d_{hop}=50[m/hop]), 22[W](d_{hop}=100[m/hop]) and 180[W](d_{hop}=200[m/hop]). Then, at least 11(d_{hop}=50[m/hop]), 5(d_{hop}=100[m/hop]) and 2(d_{hop}=200[m/hop]) relay nodes are needed.

Next, we evaluate the performance for P_{node}=20[W]. In figure 8, the result for P_{out} = 1% is shown. From Fig.10, the theoretical value and simulation results are almost equal regardless of the values of P_{node} and d_{hop}. Here, we can see that d_{hop} which minimizes P_{total} changes depending on the value of d and P_{node}. Specially, in Fig.10, P_{total} decreases in the following order. If d is within 600[m], the order is 100[m/hop], 50[m/hop] and 200[m/hop]. On the other hand, if d is over 600[m], the order is 50[m/hop], 200[m/hop] and 100[m/hop]. We show these reasons including the results of Fig.8 and Fig.9. For example, if the value of d_{hop} is larger for a fixed distance d, the following things can be said. First, the first term in (13), the transmitted power, is larger. Next, the number of relay nodes n is smaller. Therefore, the impact of the second term in (13) is different depending on the value of P_{node}. In Fig.10, the impact of the second term in (13) is larger as the value of P_{node} is larger than in both Fig.8 and Fig.9.

IV. CONCLUSIONS

We focused on the fact that the total power consumption of the whole network in multi-hop communications consists of the transmitted power and the consumed power. In this paper, we theoretically showed the effectiveness of multi-hop communications in terms of power consumption. First, we theoretically derived a closed form expression for the total power consumption in certain linear multi-hop networks. Next, we showed the validity of the derived expression using theoretical analyses and computer simulations. Therefore, to estimate the total power consumption in linear multi-hop communications, we could establish a method that uses a theoretical expression. This enables us to determine the required value immediately since our method does not use time-consuming computer simulations. Moreover, we considered the predominance of multi-hop communications compared to direct communication, in particular maximum hops and optimum hops theoretically and showed numerical values. In the future, we will analyze the total power consumption including resending after packetizing data and power consumption in a relay node.

***Abstract*—This paper describes a novel way to use the existing LTE (Long Term Evolution) communication infrastructure to monitor the change in the environment and its feasibility analysis. This system is named LTE-CommSense by the authors and can be used in many environment sensing tasks e.g. crop growth monitoring, disaster monitoring, sea state monitoring, snow avalanche monitoring, security of large unmanned landscapes etc. The key idea to this technology lies in focusing on already known signal from received signal e.g. reference symbols in the LTE communication signal frames. In the equalizer block of the receiver, the equalizer tap coefficients gets modified while training the equalizer using reference symbols, depending on the channel through which the received signal has passed through. Therefore the adaptive equalizer tap coefficients contains information regarding the channel. We propose to use these coefficients to get an estimate of change in the channel properties. Existing LTE spectrum and infrastructure will be utilized to get channel characteristics without affecting the existing communication system. After the channel information is received, this will be utilized to obtain phenomenological knowledge of the environment using ASIN (Application Specific INstrumentation) framework. We present a feasibility analysis of the novel scheme in this paper. We used LTE specific channel models from ITU (International Telecommunication Union) with AWGN noise as the dataset and nearest neighbour based classifier to validate this scheme.**
***keywords* - LTE, LTE-CommSense, adaptive equalizer, ASIN, ITU.**

I. Introduction

The first work of using Radar systems for limited amount of data communication, in the open literature is the US patent published in 1969 by Ritterbach [1]. Recently, there also has come an upsurge in activities in the field of using communication radiation for target detection and tracking using receiver only nodes. This field popularly known as passive Radar or commensal Radar ([2], [3]).

The coexistence of communication and radar systems can be broadly categorized into the following types (inspired by biological inter-species coexistence): commensal systems (one system exploits other without detrimental effect), symbiotic Systems (systems coexist and benefit from existence of each other e.g. Ritterbach patent [1], Moon-Sik patent [4] & Whitespace Radar [5]) and parasitic systems (one system affects the other in detrimental manner e.g. electronic defence & electronic warfare systems).

The proposed work will use a novel commensal radar system called CommSense [6], [7] using LTE infrastructure. We call this LTE-CommSense. The novelty of this proposed system are two fold. First of all it builds upon existing communication system to monitor the environment. This is different from any classic radar system which mainly cater to measuring the range and Doppler of a target in the scene. Secondly, and this is the major novelty of the work, LTE-CommSense does not perform correlation based processing like most existing commensal radar systems. Instead it uses the reference signal in the received communication signal to estimate the fading channels and there by predict the change in the environment.

In this paper we will show that within practicalities of simulation, this is possible and we can recognise different kinds of channels by using the channel estimation block of LTE. LTE specific six different channel models, namely ITU Pedestrian A (PA), ITU Pedestrian B (PB), ITU Vehicular A (VA), ITU Extended Pedestrian A (EPA), ITU Extended Vehicular A (EVA), ITU Extended Typical Urban (ETU) are used for this analysis. The training and recognition dataset contains multiple readings for each of these channel models each having different amount of AWGN noise added to it. Naive nearest neighbour based classifier is used to classify the recognition dataset using the training dataset as reference. The results shows promising performance of this novel scheme.

Rest of the paper is organized as follows. Section II describes the basic concept of CommSense. The feasibility analysis results of our proposed scheme is detailed in section III and conclusion & future work is provided in section IV.

II. The Concept of CommSense

In a communication system, the major thrust is on correctly estimating the received signal at the receiver. The channel model is mostly assumed to be known. Whereas in a Radar the channel is what we try to estimate. Communication systems use a range of processes and algorithms to estimate non-ergodic and fading channels in real time and try to filter out the effect of the same. Hence, the aim of CommSense will be to estimate the noise for communication systems.

Most modern communication standards and the adhering equipments cater for dynamic channel estimation. These schemes use known pilot signals in the received burst to estimate the channel and then filter the channel modulations out. Based on the above observation, we propose the Communication based Sensing or CommSense system, which will:

1) estimate the channel characteristics from the received communication signal, and
2) predict the change in the environment based on the change in the channel characteristics.

The information collected should be properly mapped from the measurements to physical events in the environment. This type of phenomenological effort is a major challenge even in conventional radar systems also [8]. To resolve this issue, different stages in the processing chain of the proposed LTE-CommSense system is shown in Figure 1. There are two sets of input and hence processing-chains in the system. The first one is a real-time system input coming from the UEs in the field. The second chain of information and processing is set by the mission control and depends on the purpose to which the LTE-CommSense will be put to for a particular time frame.

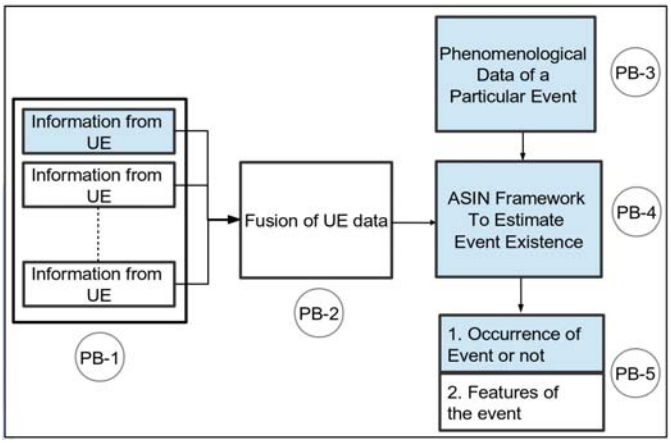

Fig. 1. Different stages in the processing chain of a LTE-CommSense system

A short description of each of the process-block (PB) are given below:

Process-block 1: Extracts information from channel equalization, done using adaptive filtering technique. In future, multiple UEs will be used to cover wider area. In that case, the adapted filter coefficients of the UE will be sent to process-block 2.

Process-block 2: Fuses all the information collected from UEs of PB-1. In this analysis single UE is considered and therefore PB-2 is bypassed.

Process-block 3: Gathers information about the event that need to be detected. This is used to train the ASIN block in PB-4.

Process-block 4: Trains and uses an ASIN block. ASIN is a pattern classification system which trains itself using the information from PB-3 and then gives prediction in real-time using information from PB-1 & PB-2.

Process-block 5: Delivers information from PB-4 to user. This information will consist of event occurrence confirmation and/or details of the event (if the event has occurred).

Bio-inspired ASIN framework [9], [10], as shown in the figure, will be utilized to obtain phenomenological knowledge about the environment. ASIN tries to estimate one or a few anomalies only instead of trying to estimate everything in the scene. Depending on what use a particular LTE-CommSense will be put into, a set of field trials will be run to gather information about the anomaly to detect and characterize. Then it can sense and characterize when that particular kind of occurrence happens in the environment. The output of the system will consist of two sets of information. First, it gives a likelihood of a particular event occurring. Secondly, given that the likelihood of that even is high enough, it gives some basic characteristics of the event also.

The proposed method will be demonstrated in indoor/outdoor environment by implementing LTE communication standard in GNURadio environment along with a software radio platform (SDR) platform. Information regarding environment changes will be extracted from very less amount of observation. Therefore, it is proposed to measure the channel from as many different locations as possible using multiple cooperative UEs. Each UE will transmit their GPS position along with the filter coefficients values. But in this initial feasibility analysis, we have considered a singe UE.

The scene of interest depends on the range of the UEs. For LTE, scene size will keep on changing and mostly will be confined to as small as the pico-cell sizes. Also, in case a LTE-CommSense system for constant monitoring of a certain area of interest, fixed UEs can be installed. The cost of such a system will be low as these will be receiver-only devices.

In LTE-CommSense, CommSense infrastructure will utilize existing LTE communication standard. The specifications for LTE was standardized in the form of Rel-8 and approved in January 2008. Target deployment started in 2010 [11]. The LTE requirements and LTE enabling technologies can be found in [12]. We are interested in LTE downlink reference signal [13] which we will use for channel estimation & equalization. In the LTE downlink, three different types of reference symbols (RSs) are provided: cell-specific RSs, UE-specific RSs and Multimedia Broadcast Single Frequency Network (MBSFN) specific RSs.

The LTE specifications don't mandate any specific channel estimation & equalization technique provided the performance requirements are met and complexity is affordable [13]. Channel estimation & equalization can be performed either in frequency domain (using channel transfer function (CTF) e.g. interpolation, least square (LS), regularized LS, minimum mean square error (MMSE), mismatched MMSE), time domain (using channel impulse response (CIR) e.g. MMSE, least mean square (LMS), normalized LMS, recursive least square (RLS), Kalman-based filtering) or in spatial domain (SD-MMSE). We will select an RS-aided channel estimation & equalization algorithm for our purpose.

III. Results & Feasibility Analysis

Six different ITU specified channel models for LTE channel analysis, namely ITU Pedestrian A (PA), ITU Pedestrian B (PB), ITU Vehicular A (VA), ITU Extended Pedestrian A (EPA), ITU Extended Vehicular A (EVA), ITU Extended Typical Urban (ETU) are used for our analysis. The multi-path profile of these six LTE channel models [13] are shown in Table I.

The highlighted blocks in Figure 1 are implemented in this feasibility analysis. In this present case, a single UE is used.

TABLE I
PROPAGATION CONDITIONS FOR MULTI-PATH FADING IN THE ITU MODELS USED FOR LTE

	Pedestrian A (PA)		Pedestrian B (PB)		Vehicular A (VA)		Extended Pedestrian A (EPA)		Extended Vehicular A (EVA)		Extended Typical Urban (ETU)	
Tap No.	Relative Delay (ns)	Relative Mean Power (db)	Relative Delay (ns)	Relative Mean Power (db)	Relative Delay (ns)	Relative Mean Power (db)	Relative Delay (ns)	Relative Mean Power (db)	Relative Delay (ns)	Relative Mean Power (db)	Relative Delay (ns)	Relative Mean Power (db)
1	0	0.0	0	0.0	0	0.0	0	0.0	0	0.0	0	-1.0
2	110	-9.7	200	-0.9	310	-1.0	30	-1	30	-1.5	50	-1.0
3	190	-19.2	800	-4.9	710	-9.0	70	-2	150	-1.4	120	-1.0
4	410	-22.8	1200	-8.0	1090	-10.0	80	-3	310	-3.6	200	0.0
5	-	-	2300	-7.8	1730	-15.0	110	-8	370	-0.6	230	0.0
6	-	-	3700	-23.9	2510	-20.0	190	-17.2	710	-9.1	500	0.0
7	-	-	-	-	-	-	-	-	1090	-7	1600	-3.0
8	-	-	-	-	-	-	-	-	1730	-12	2300	-5.0
9	-	-	-	-	-	-	-	-	2510	-16.9	5000	-7.0

Therefore, fusion of data in PB-2 is not used here. Also, Determination of occurance of the event is analyzed here. The feasibility of extracting features of the detected event will be performed in the extended work in future.

The channel profile quantifies the delays and relative powers of the multi-path components. The multi-path components in the table are not uniformly spaced in the time domain. In channel equalization, the coefficients of the used adaptive filter is dependent on the delay profile of the channel. As the channel is time-varying, each filter tap will be updated using adaptive algorithm. Depending on the changes of these channel parameters, the adaptive filter coefficients will also change. This phenomena is utilized to extract information regarding corresponding changes in the channel. The filter is be modeled as an FIR (Finite Impulse Response) filter because we receive a finite number of delayed versions of original signal at UE. We considered LMS and MMSE channel equalization method for this study.

Now, we'll analyze the feasibility to determine environment change of a noisy channel using filter coefficients of the equalizer. First we will determine equalizer tap coefficients for different LTE channel models in various channel noise conditions. This information will be used to generate training and recognition dataset for the nearest neighbour classifier. The training dataset is developed using maximum 50 images of each CIR having different amount of AWGN noise. The testing dataset also created accordingly. Given a set of adaptive filter tap coefficients, the classifier determines, to which CIR in the training dataset it best corresponds.

The analysis is performed for different values of noise variance (σ). Three different noise variances are considered: 10, 5 and 0.1 respectively. For each noise variance, accuracy is calculated for different channel lengths and two different equalizers viz. MMSE and LMS to analyze the effect of filter length on the system performance. For the LMS filter, the learning parameter (μ) is taken to be 0.004. The nearest neighbour classifier uses L_1 distance (Manhattan Distance) for distinguishing the CIRs.

The classification performance is provided in terms of performance accuracy and confusion matrix. The accuracy is the percentage of correct classification. But from the confusion matrix, we can observe in which cases incorrect classification has occurred. In this case, confusion matrix will be a $6x6$ square matrix wherein the diagonal elements corresponds to correct classification and off-diagonal elements corresponds to incorrect classification. Moreover, from the co-ordinates of these off-diagonal elements, we can determine, what is the original category of data and to what category it is classified. The recognition accuracy along with the confusion matrix for different noise variances are shown in table II, III and IV respectively.

Performance analysis of table II, III and IV proves that the idea of CommSense is feasible. Further, this limited study also showed that, MMSE is a better candidate for CommSense. For filter length more than 50, the performance accuracy of MMSE based system is consistent for the range noise condition considered. Therefore MMSE equalizer will be used in all our future experiments. Also, it can be seen that, the recognition performance improves with increase in the filter length. As the noise variance, The classification performance also increases.

As a further analysis we compared the effect of 'measure of distance' used in the nearest neighbour classifier for distinguishing the CIRs. The results are shown in table V. Here, the filter length is fixed to be 50. The noise variance of 5.0 is considered. The learning parameter (μ) for the LMS filter is taken to be 0.004. It can be observed from the result that, Euclidian distance measure is more suitable for our purpose.

IV. CONCLUSION AND FUTURE WORK

The work presented here, describes the feasibility of a novel development to the field of communication based environment sensing. It can be concluded from the analysis of the results discussed here that the proposed system is feasible in practice. CommSense being essentially a commensal radar, will not affect existing communication system in any way. Hence the required effort will be less and also it'll be a cost effective solution. Proposed LTE-CommSense will be utilized to detect

***Abstract*—This paper proposes a hybrid multi-hop network by the small UA-based wireless bridge system with satellite telecommunication system for a resilient wireless network. In the hybrid multi-hop network, small UA-based wireless bridge and satellite telecommunication system are concatenated serially via a vehicle mounted satellite earth station. The satellite telecommunication system is useful for ensuring a connection to the Internet since small UA-based wireless bridge system forms only a local network. This paper presents a brief overview of demonstration of the hybrid multi-hop network to collaborate with the cellular telecommunication network for disaster. It is shown that the hybrid multi-hop network is useful to telecommunication between an isolated and non-isolated area in the case of large-scale disaster in this paper.**

I. Introduction

In large-scale disaster in Japan, the most advanced and popular mobile phones becomes almost useless under large-scale disasters due to physical damage, electricity outage, and traffic congestion. In addition, many areas in mountains or islands were isolated due to the total damage of roads, harbors, and communication infrastructures. Under such situation, it is desired to monitor the situation in the whole of disaster area to judge, predict, and cope with disaster details. In addition, it is more desired to provide temporal communication lines rapidly deployable to the isolated areas until the recovery of ground infrastructures.

Based on the lessons learned from the past experiences, we have started research and development on disaster-resilient wireless system using small fixed-wing unmanned aircraft (UA) system in order to ensure the communication infrastructure between the isolated and the non-isolated areas. A typical UA is equipped with flight management system, propulsion system, energy storage, networked communication, miniaturized devices, and autonomous control [1]. In the case of the large-scale disaster, UAs serve as bridges among the isolated ground stations (GS) if UA has an on-board repeater. [2–5].

Through our initial experiment using small UA in the end of June 2013, we have succeeded in establishing wireless bridge networks. The two GSs separated by 12.5 km were able to exchange pictures through the UA that is located 15.1 km from a GS. In this experiment, the center frequency of the transmitter was chosen as 2 GHz and the transmit power was 2 W [5].

In order to improve the coverage and flexibility of the small UA-based wireless bridge network, we propose a hybrid multi-hop network by *small UA-based wireless bridge system* with *satellite telecommunication system* in this paper. In the hybrid multi-hop network, small UA-based wireless bridge and satellite telecommunication system are concatenated serially via a vehicle mounted satellite earth station. The satellite telecommunication system is useful for ensuring a connection to the Internet since small UA-based wireless bridge system forms only a local network. Therefore, by combing two systems, there is a possibility to rapidly deploy temporal communication lines to the isolated areas until the recovery of ground infrastructures. This paper presents brief overview of demonstration of a hybrid multi-hop network to collaborate with the cellular telecommunication network for disaster. The purpose of this demonstration is to operate the cellular telecommunication network even at the isolated area. In order to achieve our purpose, a femtocell of cellular telecommunication is installed in isolated area. The femtocell is a small base station of cellular telecommunication to improve cellular coverage within a house or a building. The femtocell requires the connection with core network to telecommunication operation. In this demonstration, the connection with core network is provided by the hybrid multi-hop network. This paper will provide the successful results of these demonstrations for accidents and disasters.

The rest of the paper is organized as follows: Section II describes the hybrid multi-hop network, and in Section III and IV experimental deployment and results are presented. Finally, concluding remarks and possible future work are given in Section V.

II. Hybrid multi-hop network

Figure 1 shows a overview of hybrid multi-hop network in this demonstration. This section briefly describes the small UA-based wireless bridge system and the satellite telecommunication system. Then we describes the hybrid multi-hop network for experimental demonstration.

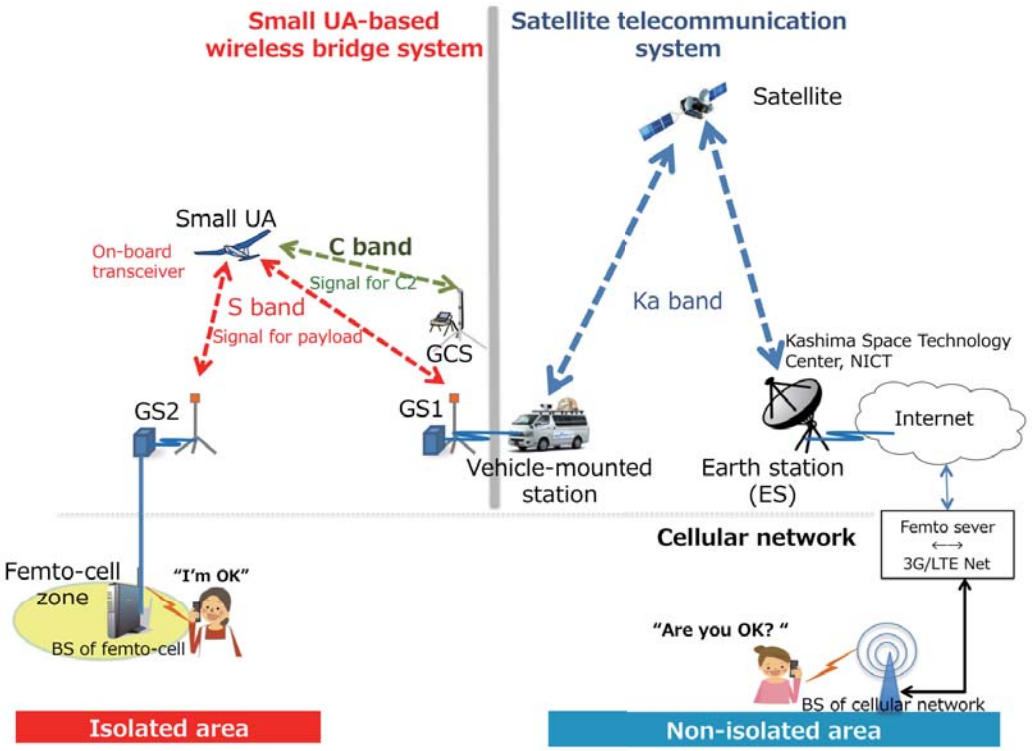

Fig. 1. Overview of hybrid multi-hop network

A. Small UA-based wireless bridge system

In the small UA-based wireless bridge system, the small UA has a on-board transceiver and relays the signal between the ground stations (GSs). The small UA circles around above the fixed area for relay communication. Table I shows the specification of small UA system. The UA system consists of a small UA and a ground control station (GCS). The payload of small UA is limited by 0.5 kg due to small airframe. The nominal endurance is about 2 or 3 hours. The control range from GCS is about 9 km. The frequency of control and non-payload communications (CNPC) is 5060 MHz and the signal power of CNPC is 1 W in this experimental measurement. The small UA can be launched by throwing and recovered by deep-stole landing. Therefore, special area such as runways is not needed for launch and landing. In addition, we can operate it even when the cars are not available due to road damage, heavy traffic jam, or gasoline shortage since the small-UA and GCS are easily hand-carried.

Table II shows the specification of transceivers for on-board and ground station (GS) for relay communication. Each transceivers for GSs and UA is equipped with a single antenna used for transmission and reception in a half duplex manner. The weight of on-board transceiver with a battery is 0.47 kg. In this experimental measurement, the frequency band of the transceiver was choose as 2 GHz and the transmit power was 2 W. The maximum range for communication between UA and GS is about 20 km. In order to relay communication, it is desired to ensure the Line-of-sight (LOS) between UA and GCs . A snapshot of small UA-based wireless bridge system is shown in Fig. 2.

Fig. 2. A snapshot of small UA-based wireless bridge system

TABLE I. SPECIFICATION OF SMALL UNMANNED-AIRCRAFT SYSTEM

Wingspan, Weight	2.8 m, 5.9 kg
Payload	Maximum 0.5 kg
Nominal endurance	about 2-3 hours
Control range	9 km
Wind speed	Maximum: 25 knots
Ceiling altitude	Maximum: 5 km
Radio frequency	5035-5085 MHz, 6 ch (experimental)
Driving power	Direct drive electric
Launch/Landing	Hand launch, Deep stall landing
Control	Manual or autonomous control

TABLE II. SPECIFICATION OF WIRELESS BRIDGE SYSTEM

Weight of GS	about 6 kg (w/o power generator)
Weight of on-board repeater	0.47 kg (w battery)
Frequency	2 GHz(experimental)
TX power	2 W
Data rate	450 kbps
Battery life	about 2 hours
Range	20 km (UA-GS)
Interface	LAN cable(1000BASE-T)
Available protocol	TCP, UDP, RTP, ICMP, ARP/RARP, etc.

B. Satellite telecommunication system

In this demonstration, we use the wideband internetworking satellite WINDS (Wideband InterNetworking engineering

test and Demonstration Satellite, also called KIZUNA). The WINDS was developed by the Japan Aerospace Exploration Agency (JAXA) and the NICT [6]. In WINDS, the frequency for communication uses Ka-band (20 GHz to 30 GHz). The WINDS includes Ka-band vehicle-mounted earth station and earth station. The earth station was installed at the NICT Kashima Space Research Center located in Kashima, Ibaraki, Japan. The user data rate of Kashima earth station is 1244 Mbps and that of the vehicle-mounted earth station is 622 Mbps. Therefore, the high-speed access to the Internet can be provided by WINDS.

C. Hybrid multi-hop network for collaboration with cellular telecommunication network

The hybrid multi-hop network consists of the small UA-based wireless bridge with satellite telecommunication systems. The small UA-based wireless bridge system provides the connection to the isolated area where broken ground infrastructures. The satellite telecommunication system proves the Internet link to the small UA-based wireless bridge system via vehicle-mounted earth station. In this experimental demonstration, we set up the femtocell at isolated area. The femtocell is the small base station of cellular telecommunication that can be installed in residential environments to provide improved cellular coverage within doors environment. In order to link the femtocells with the main core network, we uses Internet link through the hybrid multi-hop network. This configuration can provide temporal link even in a distant disaster area. However, in the case of such hybrid multi-hop network, the link quality depends on the small UA-based wireless bridge system due to the narrowband system compared with the satellite telecommunication system.

III. Experimental deployment

Figures 3 and 4 show examples of deployment and the trajectory of UA in the experimental measurement.

The area for experimental demonstration is located in the depths of mountains (1400 feet above sea level) in Kochi prefecture, Japan and it is out of coverage of cellular telecommunication network. The two GSs (denoted by GS1 and GS2) separated by about 600 m. There is no direct communication link between GS1 and GS2 such that the information can be delivered only through the relaying UA. We assumed that the area of GS2 is the isolated area and that of GS1 is non-isolated area. In the isolated area, the femtocell is located within a house close to GS2. In the non-isolated area, the vehicle-mounted earth station is located near GS1. The GS1 connects the vehicle-mounted earth station for satellite telecommunication over cable.

In Figs. 3 and 4 show two cases (denoted by case A and B) of the trajectory of UA in the experimental measurement. The flight altitude above see-level of small UA is about 2900 feet and the speed of wind is about 4 knot. In the case A as shown in Fig.3, the average of wind speed is 8 m/s, and it will be categorized as moderate breeze. On the other hand in the case B as shown in Fig.4, the average of wind speed is 2 m/s that is categorized as light breeze. In the case A, it was observed that the trajectory of is swaying due to the strong wind compared with case B. The sway of UA is one of factors that influence the communication quality.

Fig. 3. Case A: average of wind speed is 8 m/s

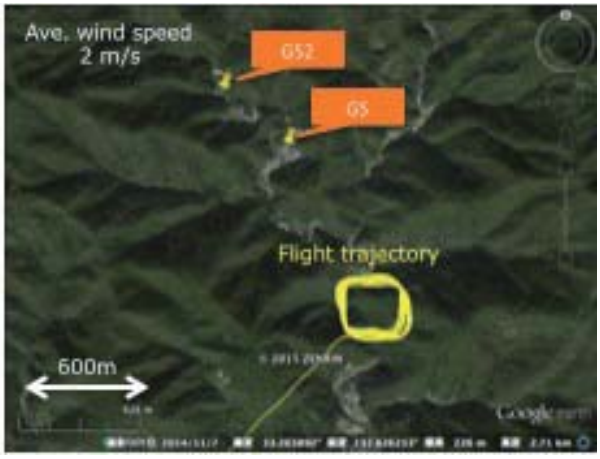

Fig. 4. Case B: average of wind speed is 2 m/s

IV. Experimental results

A. Speech quality

In this experimental measurement, we conducted voice testing using a speech quality measurement tool, such as Perceptual Evaluation of Speech Quality (PESQ) [7]. We measured the PESQ score using 3G mobile terminals, LTE mobile terminal and Skype application on LTE terminal since PESQ scores vary widely even among quality terminals.

Figures 5 and 6 show PESQ scores for various cases of mobile terminal in the demonstration system, with cases of only satellite telecommunication as a target for comparison are plotted. The 10 difference sentences of voice every terminal are inputted to the demonstration system and the scores are measured at terminal of femtocell side. Moreover, we measured PESQ scores of two cases (case A and B) for perceiving the environment influence.

From the satellite telecommunication point of view, the PESQ scores of two cases denote the same tendency and those scores depend on the mobile terminal.

On the other hand in the hybrid multi-hop network, the PESQ scores depend largely on the environment influence. In Fig. 5, the communication link between GSs often disconnects

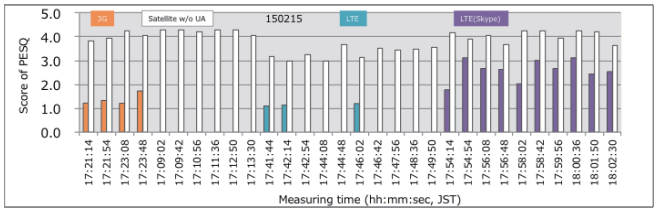

Fig. 5. PESQ scores in the case A

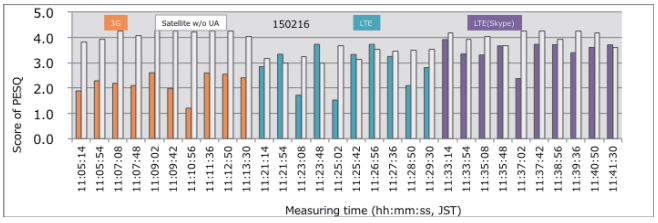

Fig. 6. PESQ scores in the case B

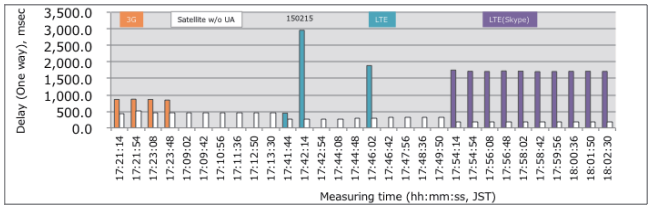

Fig. 7. One-way delay of case A

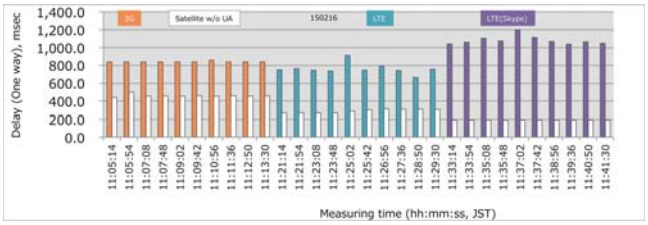

Fig. 8. One-way delay of case B

due to strong wind speed. Therefore, we could not measure all sentences of PESQ score in this case. In the case of Fig. 6, the communication link could maintain during flight. It was observed that the PESQ score of the hybrid multi-hop network exceeds 3.0 (fair) in several times. However, the variance of the PESQ score of the hybrid multi-hop network is larger than that of only satellite telecommunication system. This is because that the small-UA proves the communication link with moving relay. In order to absolutely reliability, it is necessary for the small UA-based wireless bridge system to improve the link quality.

B. Delay property

Figures 7 and 8 show one-way delay for various cases of mobile terminal in the demonstration system, with cases of only satellite telecommunication as a target for comparison are plotted. The one-way delay properties are measured at terminal of femtocell side when the 10 difference sentences of voice every terminal are inputted to the demonstration systems. Theoretically, the one-way delay of only satellite telecommunication system is below 200 msec, and the minimum delay of small UA-based wireless bridge system is 200 msec. Therefore, the minimum delay is estimated 900 msec or under at largest even if we take into account the intrinsic delay of femtocell.

In Fig. 7, we could not measure all sentences of one-way delay as with shown in Fig. 5. However, in Fig.8, it was observed that the delay of the hybrid multi-hop network varies from 740 msec to 910 msec in the case of 3G or LTE terminal. Moreover, the maximum delay of Skype application with LTE terminal reaches the edge of 1200 msec due to the addition of the processing delay of the Skype application.

V. Conclusion

We proposed the hybrid multi-hop network by small-unmanned aircraft and satellite telecommunication systems and provided overview of experiments as feasibility study of femtocell operation. The results confirm the success of the femtocell operation using the demonstration system and the validity to telecommunication between an isolated and non-isolated area in the case of disaster. The improvement of data rate and extension to multiple UAs/GSs will be left as our future works.

Acknowledgment

This work was supported in part by Shikoku Bureau of Telecommunications, the Japanese Ministry of Internal Affairs and Communications (MIC), KDDI, Softbank, docomo and TOYO corporation. The part of according to 5GHz was supported by the MIC in R&D on Cooperative Technologies and Frequency Sharing Between Unmanned Aircraft Systems (UAS) Based Wireless Relay Systems and Terrestrial Networks.

***Abstract*—Secure and Privacy Enabled Computation (SPEC) for Internet of Things (IoT) system is still at nascent stage. This is an important functionality which needs to be integrated into IoT systems specifically for Cloud deployments. Further this drives designing and deploying thousands of applications to envisage smart systems and also provides an opportunity to enable dynamic, adhoc computations in a secure and privacy manner. To realize this, feasibility of applying existing SPEC technologies and underlying cryptographic schemes for IoT is essential. In this direction, we study readiness and adaptability of existing SPEC techniques for IoT systems. Further, we propose and validate a framework to envisage Secure and Privacy Enabled Anonymous Computation for Heterogeneous (SPEACH) IoT.**

I. Introduction

Recent advances in computing Internet of Things (IoT) challenge the research community with plethora of requirements. One such requirement is Secure and Privacy Enabled Computing (SPEC). Over the years, trend in the area of IoT research was targeted at achieving; how to secure device, communication and data in IoT? Moreover, future digital world envisions Internet of Everything. For this to happen, IoT systems with large number of heterogeneous devices, gateways (GWs), public and private clouds are going to be deployed across the globe. To enable this, two preliminary requirements need to be addressed: (i). Sharing of data between different GWs anonymously for various data analytics decision. (ii). Dynamic function computation in a real time in an adhoc manner,over such data. One major challenge is; how to realize the above in a secure and privacy preserving manner? In general, fundamental questions that arise here are: What are the real time computing requirements of IoT and how many of them need security and privacy? Are the existing cryptography based solutions adaptable for IoT? To address the former, there exists several computing paradigms such as Cloud and Fog Computing. However, very little work is carried out with respect to (w.r.t.) SPEC [1]. Though privacy is addressed extensively in [2], it is limited to IoT devices only and not on SPEC.

Further from the literature survey, it is found that for Cloud and Fog computing for SPEC needs to be addressed. Though security and privacy are handled in Cloud computing, there is no extensive study of these issues for Fog computing [1], [3]. Thus as part of this paper, we study feasibility of SPEC techniques for IoT in Cloud and Fog Computing paradigms. From our study, we infer that to address later, not much work is happened [1]. In this paper, we discuss analytically and experimentally, feasibility of adapting existing SPEC techniques such as searchable encryption, homomorphic encryption, multi party computation, proxy re-encryption and differential privacy for IoT.

Hence in this direction, our main contribution in this paper is to: (i). Evaluate existing SPEC technologies and underlined cryptographic schemes from feasibility, adaptability and limitations to deploy them for IoT systems under different computing paradigms. The two aspects of SPEC considered are secure and anonymously fetch data from IoT devices (searchable encryption) and perform computation in a privacy preserving manner. (ii). Propose and validate a framework to envisage Secure and Privacy Enabled Anonymous Computing for Heterogeneous (SPEACH) IoT under a hybrid cloud computation paradigm.

Paper is organized as follows. In Section II, we describe current state of the art. Various SPEC technologies and cryptography schemes which are relevant for IoT are discussed in Section III. In Section IV, we propose SPEACH IoT framework and is validated through simulations in Section V. Finally paper is concluded in Section VI.

II. Related Work

A. IoT Architecture

OneM2M architecture is proposed for Machine to Machine (M2M) communication [4]. Different architectures involving IoT devices that connect to Cloud platform (like Azure) under the umbrella of diversified industry verticals such as health care, utility, transport and enterprise are discussed in [5]. Aneka, a new Platform As A Service (PaaS) based on .Net framework was proposed and it is a hybrid model with combination of public and private clouds.

B. Secure Computing Paradigm for IoT

To envisage SPEC, several cryptographic techniques based on Functional Encryption such as Homomorphic Encryption (HE) (partial, fully, somewhat), secure Multi Party Computation (MPC), Oblivious Transaction Protocol (OTP) and Differential Privacy (DP) are applied. In HE, idea is to operate any function over an encrypted data. For instance addition of two integers is equivalent to performing addition on two encrypted integers and then result is obtained by decrypting it. Mathematically addition of two integers x and y, $x + y = D_K(E_K(x) + E_K(y))$ (where $E_K(.)$ and $D_K(.)$ are encryption and decryption operator for HE), is equivalent to decryption of sum of two encrypted integers. These schemes are either additive or multiplicative. Craig Gentry [6] proposed

a Fully Homomorphic Encryption scheme (FHE) based on lattices which is both additive and multiplicative. Brakerski et al., devised a Somewhat FHE based on intractability assumption of Learning With Errors (LWE) [7]. This scheme is practcially implementable and hence we use this scheme for SPEC. Further, secure MPC [8] schemes involves various parties with distinct inputs and computing a result such that individual inputs are not known to each other and result of the computation is shared to every party. However MPC schemes are computationally complex and is not useful for computing complex operations.

Other aspect of SPEC is Searchable encryption (SE), which is used for searching over encrypted data [9], there are two types of schemes: (i). Symmetric Searchable Encryption (SSE, searching on ones data). (ii). Asymmetric Searchable Encryption (ASE, searching others data). Search keyword is expressed in through a regular expression or a token. We implement ASE [10] scheme for searching over large data encrypted using public key encryption and search this using a regular expression. Advantage of this scheme is that it also supports partial searching.

Finally, we discuss some of these techniques which are utilized for IoT to perform SPEC. IoT is modeled as Cooperative Distributed System (CDS) in [11]. This is a computation platform wherein devices share information and capability among each other in a privacy preserving manner (achieves at least 50% of device privacy) by Differential Privacy (DP) with the help of broker. However this scheme supports partial privacy preserving computation involving many parties. Further for smart meter data analysis, DP based scheme is used in [12], [13].

III. Privacy Enabled Computing in a Nutshell

Typical characteristics of IoT are heterogeneity of (i). Devices (limited computing and battery power) (ii). Connectivity and interfaces between devices. (iii) topologies (hierarchical, random). These features causes overhead in designing and deploying applications for various purposes such as smart infrastructure (home, city, grid, ...) in a secure and privacy preserving manner. Further these applications demand real time computation for IoT systems without losing security and privacy of data and devices. Existing Cloud and Fog computing paradigms address privacy issues in a very limited way and hence SPEC frameworks needs to be augmented. In this section, we bring out some of the very important frameworks and their capabilities, strengths and weekness w.r.t. augmenting it to the existing computing paradigms for IoT.

A. Cryptography for Privacy Enabled Computation

To envisage SPEC for IoT, efficient cryptographic techniques are essential. In this section, we examine (c.f. Table I) some of these relevant techniques from: (i). utility, (ii). computation complexity, (iii). level of security and (iv). limitations perspective. Though goal of any IoT system is to achieve high utility with higher level of security and that needs to be achieved with lower computation, there is a trade off among (i), (ii) and (iii). Thus efficiency of SPEC for IoT depends on the underline cryptographic techniques employed.

From the Table I, we infer that for less complex computations, MPC schemes are better (in particularly 2PC) and mainly aggregation operation is involved. This technique is suitable for IoT, since some of the IoT systems are hierarchical in nature and computations are distributed. However malicious parties perturb the result of computations and in order to overcome this a stringent traitor tracing algorithms are needed which are computationally expensive. Further FHE schemes are useful, wherever arithmetic computations are performed. This can be used in any IoT systems such as smart meter and smart grid applications. Though theoretically, these schemes support strong security at the cost of large key size, they incur higher computational overhead when large number of successive operations are performed (due to re-linearizion technique in FHE) [7]).

For privacy enabled logical operations, Ordered Preserving Encryptions (OPE) are better than garbled circuit based approach (suitable for one time execution) for IoT in terms of computations. DP scheme is useful for statistical query processing over a large data set and in particular it is useful for offline IoT analytics. Though zero knowledge protocols are useful to verify integrity of the software (Verifiable Computation), they are computationally expensive. Hence this technique is preferred only in case of critical applications and it is not suitable for general purpose IoT applications. Private Information Retrieval (PIR) is an interactive tool applicable to retrieve data based on secret index, which is computationally expensive and hence not applicable for IoT applications. Thus the design of SPEC for IoT is greatly influenced by the underlying cryptographic techniques. In the next subsection, we analyze existing SPEC frameworks which uses some of these underlying cryptographic techniques.

B. Privacy Enabled Computation Frameworks

Some of the prominent SPEC models which are relevant for IoT systems are tabulated in Table II. We examine these models from different capabilities: (i). Different types of privacy enabled computations (searching, function evaluation). (ii). Computing point (computation done either at Device, Gateway or Cloud). (iii). Whether the computation is interactive or non interactive? (iv). Data security point (Whether data is encrypted at Device, Gateway or Cloud?). (v). Underlying cryptography technique. From IoT perspective, these factors are relevant and different types of applications or use cases need some subset of these capabilities of SPEC.

From the Table II, it is evident that Mylar and CryptDB are applicable for computation involving large databases. Limitation of these schemes are that they do not support all types of computation. Hence this is useful to perform offline data analytics for IoT. Secondly in [18] the authors have reported some frequency analysis based attacks on CryptDB wherein the identites can be inferred by matching encrypted records of CryptDB with public database. DCapBAC and UPECSI are used for authentication purpose and can be plugged to IoT framework. Mariana proposes different MPC schemes to compute and search on encrypted data. These schemes are lightweight and hence useful for IoT. In case of smart meter technology, several smart meters data are aggregated at a gateway level and there by they are suitable for IoT systems, where aggregations are required. Riposte is a secure messaging protocol which can be used for message passing during any

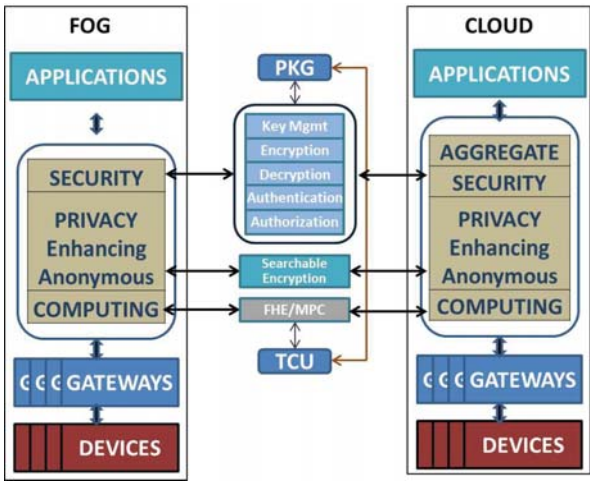

Fig. 1: Architecture diagram of SPEACH framework

computation. DJoin protocol is used for computing on distributed databases. Hence these two schemes are candidates for offline data analytics. From this analysis, we infer that, though these technologies and underlying cryptography schemes are useful in designing specific applications (for instance smart meter data analysis, large data analytics applications), they are not directly deployable for IoT systems in general. Careful integration of these technologies is very essential to envisage secure anonymous data retrieval and SPEC. Further some of these techniques are computationally expensive and don't support SPEC fully. Hence this requires a need of Trusted Computing Unit (TCU) which is capable of decoding partial results of SPEC and through which fully SPEC is enabled. Hence to address these limitations, we propose secure and SPEC for IoT under hybrid Cloud in the next section.

IV. Secure and Privacy Enabled Anonymous Computation for Heterogeneous (SPEACH) IoT

Proposed Secure and Privacy Enabled Anonymous Computation for Heterogeneous IoT is illustrated in Fig. 1. It assumes that basic functionality of security framework (Confidentiality, Integrity and Authentication) is available and on top of this, SPEACH is envisaged. Note that SPEACH framework can be augmented on existing IoT architecture such as OneM2M IoT architecture [4]. Two Important entities of SPEACH are: (i). Anonymously retrieving encrypted data (SE) from different IoT Devices, Gateway or Cloud. (ii). Securely computing over encrypted data. As discussed earlier, in case of existing SPEC techniques, certain computations cannot be performed in a privacy preserving manner fully. Hence there is a need for TCU to enable it (c.f. Fig. 1). TCU is capable of decoding partial results and facilitate computing in a privacy preserved manner. Thus flexible design of SPEACH is adaptable to support SPEC for hybrid Cloud architectures. Deployment of SPEACH for Cloud and Fog computing are similar, except that in case of Cloud computing the aggregation function is embedded at its place while in Fog the computing is pushed to the endpoints. Further at Cloud, SPEACH is capable of performing SPEC in an offline manner.

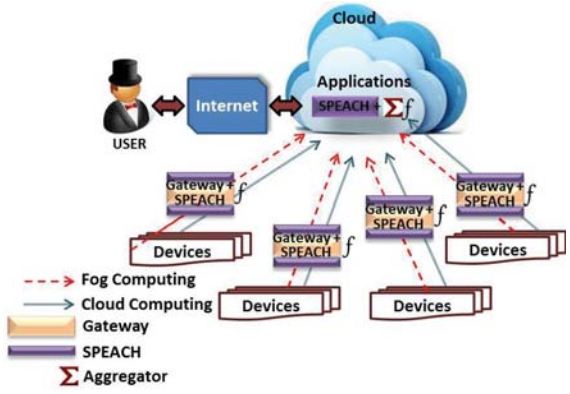

Fig. 2: Deployment of SPEACH framework

Now, we explain how SPEC can be performed for an IoT application which illustrate hybrid cloud computing through SPEACH with an example (c.f. Fig. 2). Consider a scenario, where an user invokes an application at Cloud to compute a utility function (say current power consumption). This is performed interactively in several steps. Initially the application requires data from different devices (say smart meters). Information about these devices (such as locations, relevant gateway) are stored in encrypted form at Cloud and gateway. To retrieve this information anonymously, SE algorithm of

TABLE II: Privacy Enabled Computing Frameworks

Sl No.	Scheme	Crypto Technology	Operation	Computing Entity	Interactive	Code Integrity	Authentication	Encryption

9.	DJoin [16]	DP	Comp	Cloud	Yes	Yes	No	Asymmetric

SPEACH is invoked using the information about the devices. After obtaining relevant information, application requests relevant GWs (let us say k number of gateways among n GWs: $\{G_1, G_2, \ldots, G_k\}$) which are deployed at different locations to compute SPEC. Subsequently, each gateway (G_i) fetches encrypted data from intended devices (which are connected to them) and performs required SPEC: $f_i(D_{i_1}, D_{i_2}, \ldots, D_{i_k})$. Note that $D_{i_1}, D_{i_2}, \ldots, D_{i_k}$ are encrypted data from devices of i^{th} gateway. After this, these GWs forward encrypted result to the Cloud application. Then at Cloud, application performs SPEC based aggregation in order to compute resultant function ($f = \sum_{i=1}^{k} f_i$). Finally result is sent to user and subsequently user decrypts the end result.

V. Simulation Results

A. Simulation Setup

We validate SPEACH framework through simulation. We implemented and simulated IoT architecture deployment (c.f. Table III) as described in Fig. 2 with 100 devices, 5 GWs (20 devices per GW) and a hybrid Cloud and SPEACH is deployed at GWs and Cloud as well. We implement two major functionalities of SPEACH (i). Searchable Encryption [10]. (ii). SPEC based on and SW-FHE [7]. As part of encrypted search function, IoT devices encrypt data (about type of device, location, data model, gateway, etc.,). This data is stored at Cloud Database based on Damgard-Jurik crypto system. An User/Application initiates SE query with encrypted keywords (such as sensor location, id, etc.,) and is executed interactively between both User/Application and Cloud. Advantage of this scheme is that algorithm supports all types of encrypted search (prefix, suffix or full keyword search). We tabulate computation time at Application/GW and Cloud for different number of records. Data is encrypted using key size of 8 bits. Database and queries are prepared such that for each execution, number of search hits is 30% of total number of records.

Further to realize SPEC based on FHE, we compute $f = \sum_{i=1}^{100} a_i * b_i$ (where a_i and b_i are encrypted integers of size 8, 16, 32, 64 and 128 bits) at Cloud and GW (Fog computing). In Cloud Computing, IoT devices encrypt data and send it to the Cloud via GW. Computation is performed by the Cloud. In case of Fog Computing, each GW receives encrypted data from 20 devices and computes ($f_i = \sum_{k=1}^{20} a_{i_k} * b_{i_k} : i = 1$ to 5 and each a_{i_k} and b_{i_k} are data from sensor belong to GW G_i). Using SPEACH, all the GWs send computed values to the Cloud. At Cloud, $f = \sum_{i=1}^{5} f_i$ (aggregation function) is computed and final result is sent to user/application in encrypted format and subsequently user/application decrypts the result.

Database	MySQL 5.6

B. Performance Analysis

To enable secure and SPEC, retrieving data anonymously is achieved through SE. Performance of SE algorithm is very crucial. Hence we conduct performance analysis and Fig. 4 describes performance of SE, which involves interactions. Higher the complexity of the search query and larger the search space, more will be the number of interactions and thus more time it takes to search. This is evident from the plot and further note that time taken for client computation is less. Hence this scheme is suitable for IoT system. After determining data source locations, we perform actual SPEC computation. Performance of the computation depends on performance of data encryption, SPEC and decryption. Performance results are plotted w.r.t. computation time for various bit sizes (c.f. Fig. 5). We observe that encryption time is more than that of decryption and in case of IoT systems, encryption can be outsourced to a GW (to increase lifetime of IoT devices). Computation time w.r.t. SPEC performance is plotted in Fig. 5 for Cloud/GW(Fog) paradigm. Further we observe that computation time for a given function $f = \sum_{i=1}^{100} a_i * b_i$ is less at Fog than that of Cloud. Note that for both Cloud/Fog computing to simplify simulations, we didn't include communication overhead (which also affects performance of SPEC). From the results, we infer that for real time, dynamic and adhoc computations, where function needs to be computed in a distributed and shared manner, fog computation is better and also for predetermined computations, hybrid computation model is a better approach, wherein GWs compute the given function and aggregation is also done at GW. For offline SPEC computation in IoT systems (useful for predictive analysis), Cloud computing is preferred.

VI. Conclusion

Emerging applications for Cloud based IoT systems require secure and privacy enabled computation (SPEC). In this paper we established the fact that existing SPEC and underlined cryptography schemes cannot be directly deployed for IoT systems. Most of these techniques are computationally expensive and not fully privacy enabled. Further to envisage anonymous

data sharing among different gateways in IoT and also to perform dynamic and adhoc SPEC in IoT system a secure and SPEC framework is essential. In this paper, we proposed and validated SPEACH IoT framework. As part of our future work, we will deploy SPEACH on real Cloud IoT systems and benchmark the performance and also work towards realizing robust SPEACH, which is resilient to different security attacks.

***Abstract*—NerveNet is a regional-area platform network for providing resilient information sharing and communications even if the access to the Internet is impossible in emergency situations. It is composed of multiple basestations interconnected each other by a variety of Ethernet-based wired or wireless transmission systems, configuring a mesh-topological network. Database and service functions operate on each basestation in a distributed manner. In collaboration with Shirahama town in Wakayama prefecture in Japan, we deployed a NerveNet experimental network in the town as the town's resilient network. It is composed of nine basestations interconnected by 5.6GHz Wi-Fi and FWA, providing users with localized web access, voice phone, and messaging as well as ordinal Internet access via 2.4/5GHz Wi-Fi.**

Keywords—mesh network, resilient network, IoT, NerveNet

I. INTRODUCTION

The East Japan Great Earthquake and tsunami on March 11 badly damaged Japanese information and communications system. Many of the access networks and core networks in the areas were down due to link disconnections, system failures, and blackout. About 14000 cellular basestations stopped mostly due to power outage. Optical fibers, metal cables, and telephone lines were cut. These failures made it impossible for the people in the quake-hit areas to get, upload, and share information since they could not access to application servers on the Internet. People in other regions including Tokyo also could not make prompt phone calls due to the limitation of call acceptance for avoiding large-scale breakdown of their networks. Therefore, it was not easy to confirm family's safety and to figure out the extent of the disaster damages.

What we learned from those experiences is the importance of "bypass networks". See Fig. 1. Let cellular and fixed access networks be a main road. Usually, it is the best for us to use the main road for our communications. However, we learned that the main road might stop. Therefore, in order to prepare future disasters, we need to assume that the main road might stop and to prepare bypass roads besides the main road. The bypass roads composed of multiple, different networks could be better than that of a single network to increase tolerance to disasters. One of the bypass networks is disaster-resilient mesh-topological network, called NerveNet.

Figure 2 shows a concept of our bypass networks created in 2009. NerveNet, UAV radio relay system, and satellite system configure a resilient network. NerveNet covers a local-area communications while UAV radio relay and satellite systems provide communications between isolated, damaged areas and others. According to this concept, we developed and deployed a large-scale testbed network systems including the three systems in two campuses of Tohoku University March 2013 [1].

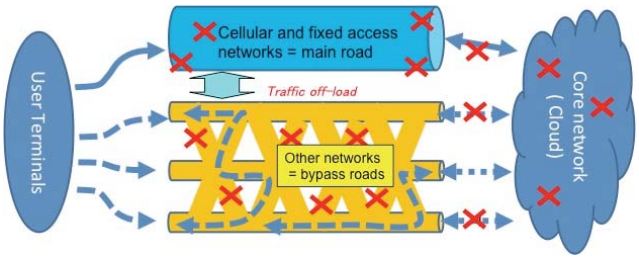

Fig. 1. A key to prepare future disaster is to build bypass networks besides main networks for increasing probability of our communications.

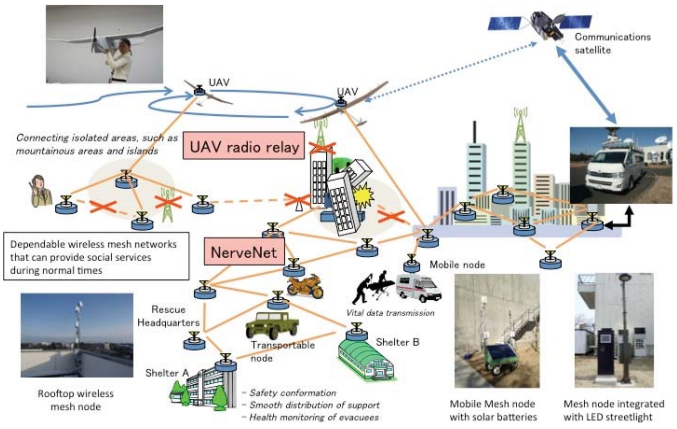

Fig. 2. Concept of bypss networks.

II. OVERVIEW OF NERVENET

A. Concept

NerveNet was originally designed as an access network of future network, future Internet or new generation network [2-4].

It is a regional network that provides various context-aware services with use of sensors and actuators. We named it as NerveNet since it works like the nervous system of the human beings.

B. *Physical Architecture*

NerveNet is composed of multiple, distributed basestations interconnected with each other by means of a variety of Ethernet-based transmission systems such as optical/metal Ethernet, WiFi, FWA, satellite, and unmanned aerial vehicle (UAV), configuring a mesh-topological network as shown in Fig. 3. A set of a basestation consists of one main unit and several pairs of a radio transceiver and an antenna. One pair is for accommodating users' WiFi appliances while others are for interconnecting basestations. Each transceiver is connected to and powered by a main unit through a PoE Ethernet cable. A typical set of basestation consumes 50 Watt or less, enabling its operation by solar power only as necessary.

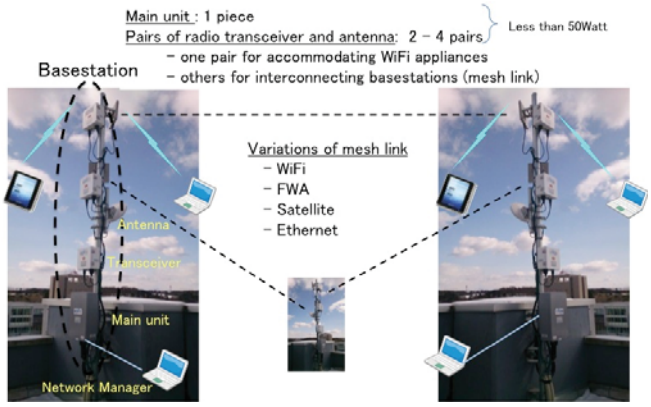

Fig. 3. Configuration of NerveNet.

A basestation main unit consists of a LAN switch and a CPU board for controlling the switch, providing packet transmission and applications using distributed database among all the basestations over a mesh network. This simple configuration promises its low price at its commercial phase. A network manager, which can be operated on a PC, is necessary to configure the network at the first stage. It is, however, not necessary after the network starts working because the network operates in a distributed manner without such central controller. As NerveNet is basically a LAN-based network system, ordinal computers and servers can be connected directly with Ethernet cables.

C. *Main Features*

NerveNet features communications and networking, and information processing as in Fig. 4.

The first is the provision of fast multihop Ethernet-frame transmission over a mesh-topological layer-2 network. Upon a request of a communication between any two users at different basestations, NerveNet assigns one of multiple virtual LANs to the communication. When the virtual LAN suffers from a link disconnection or a failure of a basestation on the route, the communication is switch over to another virtual LAN.

The CPU board in a basestation performs information processing, providing distributed database management system across all the basestations. Any data such as user data, a local map, evacuation points and routes, AED locations, and sensor data, can be data entry and shared in the network. Although the capacity of the CPU board is small, important information needed in emergency situations can be stored in the database so that users can get it even if they cannot access to the Internet.

Thus, compared with existing Internet-depend, tree-topological network systems, NerveNet is tolerant to link disconnections and system failures.

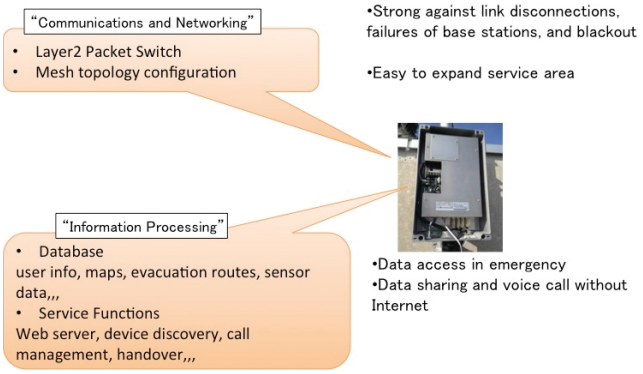

Fig. 4. Features of NerveNet: "communications and networking" and "information processing".

III. Architectural Paradigm Shift

A key of NerveNet is a paradigm shift of both networking architecture and application architecture as illustrated in Fig. 5.

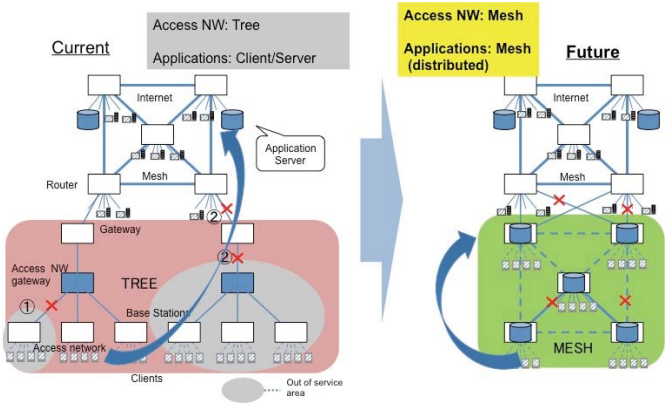

Fig. 5. Key point of NerveNet: shifting architecture of network from tree to mesh and application architecture from remote (cloud) to local.

Although tree-topological network is efficient in providing communications between remote users, it is weak against failures. Even if an access network is working and mesh-topological Internet is strong against failures, our smartphones or clients need to communicate with application servers on the Internet. Namely, this is client-server or point-to-point architecture in the application layer. This is very weak against failures and overloads of servers.

NerveNet is a mesh-topological access network and provides distributed database and information processing

functions over it. This makes the network and application services strong against failures and makes it possible to continue certain services without the user of resources on the Internet. NerveNet can also provide faster response services to end users and actuators compared to remote cloud-based architecture. This is another benefit to be emphasized.

IV. Field Experiment in Shirahama Town

A. Shirahama Town

Shirahama town is located in about the middle of Wakayama Prefecture in Japan as depicted in Fig. 6. It has a small population of about twenty-two thousands but a large number of tourists around three millions a year come for sightseeing and recreations. More than seventy thousand tourists from abroad visited last year. Shirahama town, on the other hand, has to prepare against natural disasters such as typhoons and earthquakes. In particular, it has to provide against a mega-scale earthquake and tsunami predicted by Japanese government to take place in the Nankai Trough off the Pacific coast. Several-meter to twenty-meter tsunami is predicted at the coast of Shirahama as shown in Fig. 7. This motivates the town to demand a system for ensuring safety of residents and tourists.

Fig. 6. Location of Shirahama town.

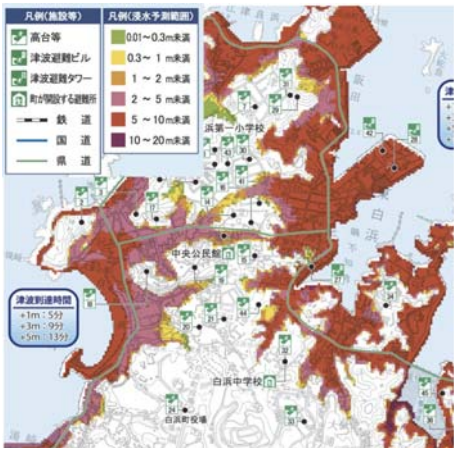

Fig. 7. Estimated tsunami heights in Shirahama.

B. Goal

Shirahama town office and NICT made an agreement of a collaborative work for resilient network in December 2014 and started preparation of a field experiment of NerveNet in the town. The goal of the experiment is to make clear the effectiveness and sustainability of NerveNet in ordinary and emergency situations in collaboration with local authorities, organizations, residents and tourists, creating a reference model “Shirahama model”. It could be applied to other regions having similarities with Shirahama such as location (coast side), topography, types of disasters, etc.

C. Setup of Experimental Network

We deployed nine basestations in total in the region and configured a NerveNet in May 2015 and started a field experiment that will last until March 2016 at least. The configuration is shown in Fig. 8. Eight basestations are in the town and another in the neighboring “Tanabe” city. Locations are Shirahama town hall, Shirahama hospital, Shirahama open-air hot-spring bath called “Shirara-Yu”, “Minakata Kumagusu” Museum, three hotels (hotel A, B, and C), a restaurant near “Senjo-jiki” in Shirahama town and Wakayama Prefectural Information Exchange Center “Big-U” in Tanabe city. Each basestation is installed on the top of each building. A commercial FWA system in the 4.9GHz (IEEE802.11j) is used for the inter-BS link between Big-U and Hotel A at a distance of about 5 km. Wi-Fi transmission systems in the band of 5.6GHz (W56) are used for other fifteen links including the link of around 2 km between Minakata Kumagusu Museum and Senjo-jiki across the sea. Basically a channel of eleven channels in W56 band is assigned to each link to avoid interference as best as possible. Connection modes of W56 links range from 6Mbps to 54Mbps depending on link distance.

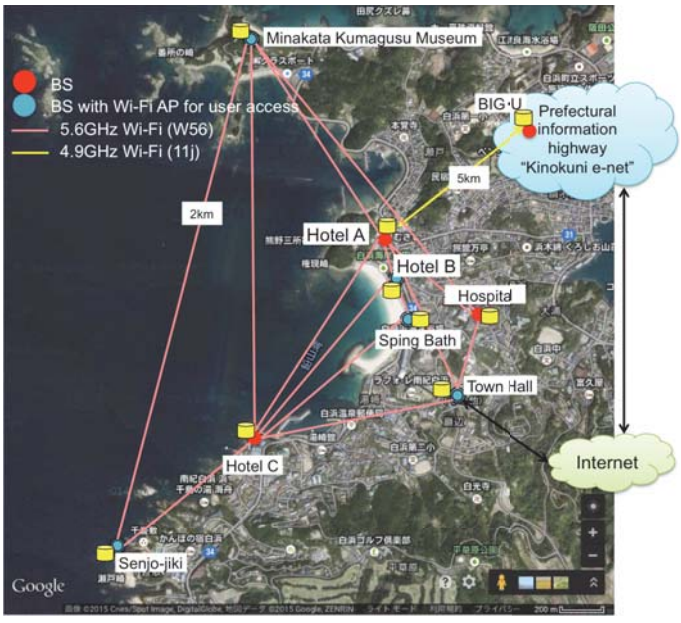

Fig. 8. Configuration of the experimental network.

It has two connections to the Internet to improve resilience. The BS at Shirahama town hall is connected to NTT’s Internet access network while another at Big-U is connected to the

Internet through Wakayama Prefectural Information Highway "Kinokuni e-net". Wi-Fi access point for user access operated in the bands of both 2.4GHz and 5GHz is also installed to provide access to this network as well as public free Internet access via Wi-Fi to residents and tourists at five BSs: Minakata Kumagusu Museum (see Fig. 9), hotel B near Shirarahama beach (see Fig. 10), Shirara-Yu near the beach, Shirahama town hall, and Senjo-jiki.

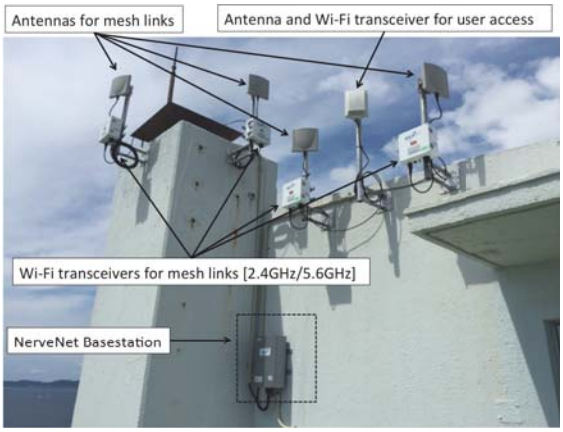

Fig. 9. Installed equipment at Minakata Kumagusu Mueseum.

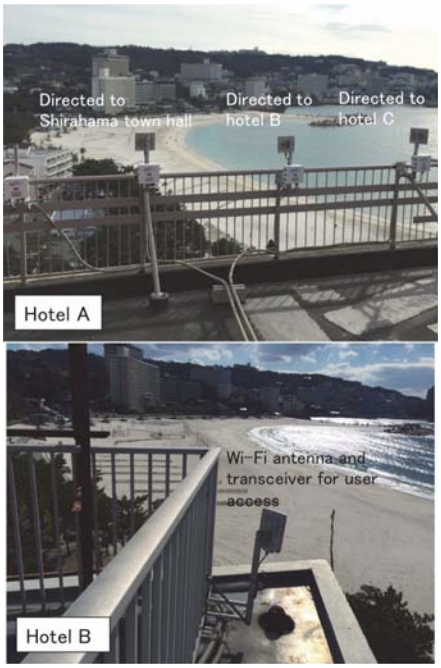

Fig. 10. Three Wi-Fi antennas and transceivers for mesh links at Hotel A (top) and the one at Hotel B for user access from the beach (bottom).

D. Applications

The experimental network provides four applications to users (Fig. 11). The first is Internet access. The second is geo-localized data access through a web server function running on each basestation. Using this functionality, potentially we can present different contents and different applications to users accessing to the network from different locations without using power-consuming GPS-based positioning. In the experiment, we provide a shelter map around the connecting basestation (Fig. 12). Furthermore, "Kokodake BBS" is provided (Fig. 12). Users can enter their notes for their memory and footprint in case of emergency. The notes stored at a basestation can be read only at the same basestation. The third and fourth are intranet voice call and intranet messaging using a dedicated application software for Android OS. Because NerveNet have call management and mobility management functions based on SIP, these applications can work without any servers on the Internet.

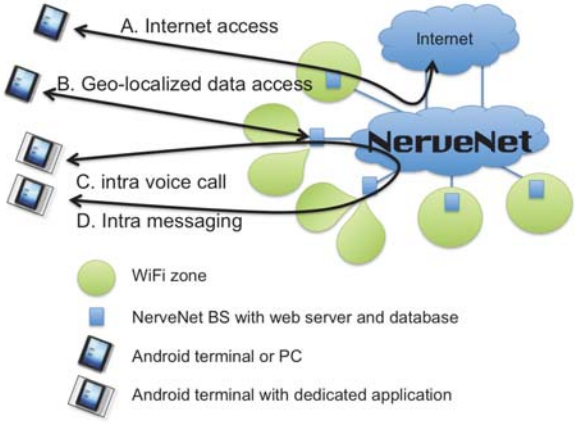

Fig. 11. Available applications in the experiment. Applications B, C, and D do not need the Internet.

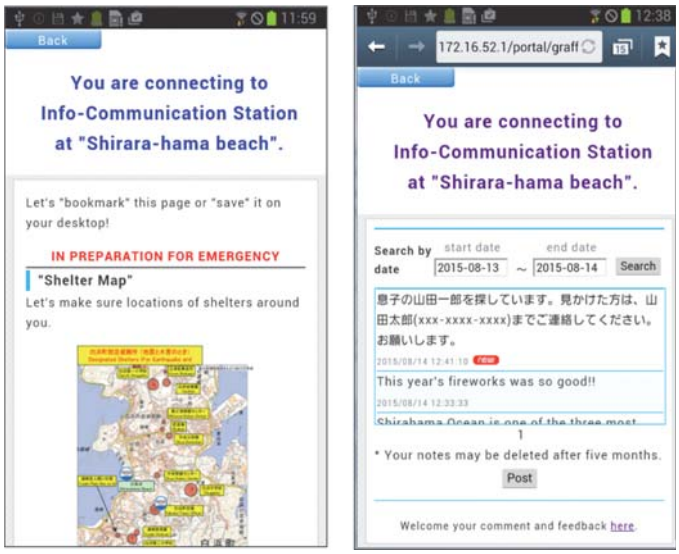

Fig. 12. Top page of a basestation's web (left) and "Kokodake BBS" where you can enter your notes (right).

V. Use Cases and Benefits of NerveNet

According to interviews conducted by NICT and companies with several tens of Japanese local governments on their needs and problems, we found that they want to provide public local services at low cost in a safe manner. They include distribution of sightseeing information, surveillance of roads and rivers, warning and alert, road traffic control, sharing of bicycles, surveillance of garbage dumps, local security such as

outdoor monitoring of children and elderly people and indoor monitoring of elderly people living alone, prevention and control of wildlife damage, and position reporting of local buses. Another interview with local governments that suffered from The Great East Japan Earthquake showed that they had needed a tool for talk or information exchange between staffs in the situation where neither cellular nor fixed networks had been available. They do not mind if it is not available anywhere. They would satisfy even if it were available at very limited locations in case of emergencies. Thus, NerveNet could be a solution to these needs and problems. Figure 13 illustrates an image of NerveNet and its use scenes in an urban area.

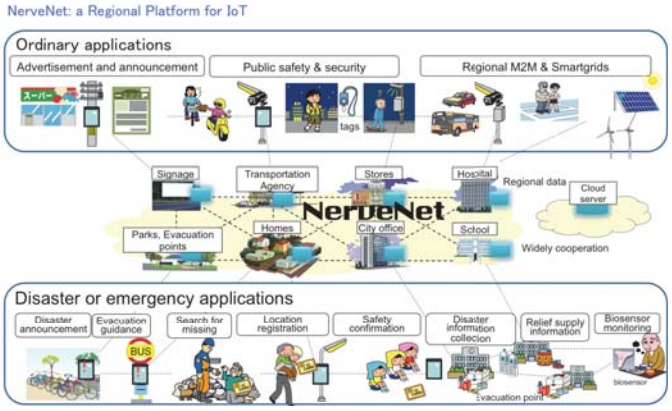

Fig. 13. Use scenes in an urban area.

Functions and benefits of NerveNet are summarized as follows.

1. It works as a regional LAN to directly interconnect a local government, authorities, companies, and residents as well as IoT devices such as digital signage and monitoring sensors, enabling two-way data communications such as collection, exchange, and distribution of any information including sensor data, voice and video, and messaging.
2. Because of resilience of both networking based on layer-2 mesh configuration and information processing based on distributed computation on each basestation, even in case where public networks and the Internet are not available, it is expected that it distributes important information on disasters, evacuation and rescue, food supply, etc., and it provides voice and message communications for government staffs and residents at a certain possibility.
3. It is possible to deploy an outdoor regional network at low initial cost and maintain it at low running cost because NerveNet can be configured with the use of variety of transmission systems including unlicensed radio systems. It is not necessary to deploy a network from the scratch. Existing fiber-based local-government network (called regional intranet in Japan) can be updated to NerveNet by installing NerveNet basestations as LAN switches and adding several new connections between basestations to obtain resilience. Commercialized wireless mesh network products cannot make such wired and wireless hybrid network because they assume to use Wi-Fi radio for mesh link and do not have enough Ethernet ports.

NerveNet applied to a rural area provides universal access for users to the Internet at low cost, gives security against disasters and sensing and alert services, and allows local communications without the outer networks such as the Internet and telephone networks, as depicted in Fig. 14. There are these demands not only in developing countries but also in Japanese rural areas.

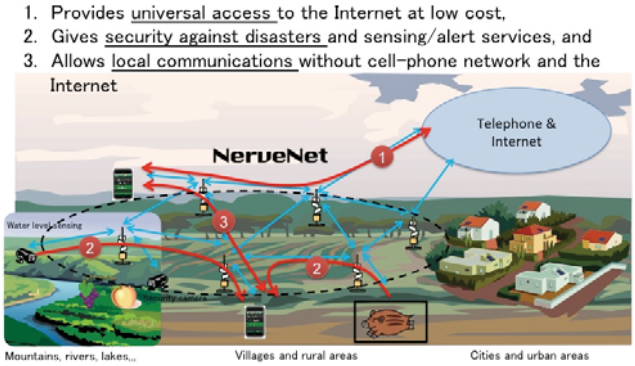

Fig. 14. Use scenes in a rural area.

VI. Concluding Remarks

NerveNet, which was originally designed as an access network of Future Network, has been developed as a resilient regional network platform. We have been gaining many attentions to this technology from IT companies, local governments, hospitals, fire departments, and authorities in ASEAN countries because probably there would be no such technology that can provide data access, data exchange, data sharing, voice call, and messaging without the Internet at low cost and low power. We will continue the experiment to obtain data to make clear the effectiveness and sustainability, creating Shirahama model for the reference to others.

Acknowledgment

We thank Mr. Makoto ITANI of the mayor of the town and Mr. Kazuhiro SAKAMOTO of the town office for their understanding and support of the experiment.

***Abstract*—Spectrum Sensing is a prime functionality that allows cognitive radio for opportunistic use of vacant bands in order to improve the radio spectrum utilization. Sensing the low signal-to-noise ratio (SNR) signal is essential to facilitate the quality of service for both licensed and cognitive users in a cognitive radio network. Though, there exist numerous sensing algorithms, their performance or reliability is sensitive to noise variance uncertainty, in particular in low SNR scenario. In this work, we propose a detection method based on fractal dimension of cyclic spectrum estimates of the received signal. Since the noise uncertainty is unknown to the detector, the noise variance uncertainty is assumed to be a random number which follows uniform distribution within the constraints. In addition, the proposed method is extended to cooperative sensing and analysed its performance by applying hard decision fusion techniques. The results reveal that the proposed method is less sensitive to noise variance uncertainty and improves the probability of detection under low SNR regime.**

***Index Terms*—Cognitive Radio, Cooperative spectrum sensing, spectral estimates, fractal dimension, Noise variance uncertainty.**

I. Introduction

The tremendous ongoing growth of wireless communication has resulted spectrum shortage which intern becomes an obstacle for growth of new wireless devices. However, recent statistical studies on radio spectrum usage have shown poor utilization of frequency bands due to rigid licensing policies. The spectrum shortage and inefficient utilization of spectrum make it necessary to develop a cognitive radio (CR) technology to exploit the existing radio spectrum opportunistically. One of the key challenges of the CR is to detect the presence or absence of the signal in a desired frequency band at low signal-to-noise ratio (SNR) with the constraint that it should not interfere with the primary user (PU) [1]. To achieve this, quite a few signal detection methods have been proposed over the last two decades, such as energy detection, entropy detection, cyclostationary detection, eigenvalue based detection, covariance based detection, and interference based detection etc.,[2], [3]. Each one of these has their own advantages and disadvantages.

Although, various detection techniques are proposed, all the methods require an estimate of the noise power a priori for fixing the value of the detection threshold. However, noise level in channel may change over time, which yields noise uncertainty. The traditional sensing algorithms are sensitive to noise variations in the received signal [4]. Nevertheless, many of the works considered energy detection due to its ability to work irrespective of signal format to detect, general applicability, and its simplicity [5], [6]. Because of the noise uncertainty, in practice, it is very difficult to obtain an estimate of the exact noise power. In the traditional sensing algorithms noise power is assumed to be known a priori and assumed to be Gaussian to design the detection threshold. In fact, real time statistical behavior of the received data at CR differs from the Gaussian approximation [4], [7], [8]. Hence, to deal with the noise uncertainty, we assume that noise uncertainty is uniformly distributed in the range as in [4]. The effect of noise uncertainty on generalized energy detector (GED) performance is studied with assumption of different uncertainty modeling [9]. The author introduced a signal detection method based on complexity of received time domain signal at cognitive radio. But, the performance of the above detectors at low SNR is very poor. In recent past, geometry of fractals and the mathematics of fractal dimension provide useful tools for a variety of scientific disciplines, in particular, the study of noisy signals [10], [11]. Many methods exist to compute the fractal dimension, each method has its own theoretic basis. The most popular methods among them are box counting method, minkowski dilation method, extended counting method, differential box counting method, a blanket method or frequency analysis, variogram method, isarithm method, and triangular prism method, etc., [12]. In this work, Higuchi Fractal Dimension (HFD) method is applied to find the roughness/complexity in estimated spectrum at one particular cyclic frequencies.

The focus of the current work is to detect the PU signal reliably in low SNR regime under noise variance uncertainty. To address the noise variance uncertainty in sensing, we propose a robust method which compute the Higuchi Fractal Dimension (HFD) of cyclic spectrum estimates of received signals. The method is based on the fact that the roughness of the spectral estimates varies as the SNR of the received signal changes. In addition, cooperative sensing performance based on proposed technique is analyzed under noise variance uncertainty by applying hard decision fusion logic [13].

Rest of the paper is organized as follows. Section II presents proposed sensing algorithm under noise uncertainty. Section III presents hard decision based fusion methods for cooperative

sensing. Simulation results are discussed in Section IV. Finally, our conclusions are presented in Section V.

II. Sensing algorithm under noise variance uncertainty

The objective of spectrum sensing is to discriminate between the following two hypotheses H_0 (PU signal active) and H_1 (PU signal inactive) in a desired frequency band.

$$H_0 : r(n) = w(n),$$
$$H_1 : r(n) = hs(n) + w(n), n = 0, 1, 2, \ldots, (N-1),$$

where $r[n] = [r(0), r(1), r(2), \ldots, r(N-1)]$ is the received signal sequence received by the CR user, N is the sample size. The channel gain (h), transmitted signal $s(n)$, and the $w(n)$ is additive white Gaussian noise (AWGN) with mean zero and uncertain variance. We assumed that the channel is time invariant during the sensing period.

In practice, the average noise power ($\hat{\sigma}_w^2$) is known [9]. But the actual noise power (σ_w^2) at fixed time and location is different from the average noise power, which is responsible for noise uncertainty. Hence, we can define noise uncertainty factor as $\beta_u = \frac{\hat{\sigma}_w^2}{\sigma_w^2}$. Let the upper bound on noise uncertainty factor in dB be φ which is defined as, $\varphi = \sup\{10\log_{10}\beta_u\}$. we assume that noise uncertainty factor β_u in dB is uniformly distributed in the range $[-\varphi, \varphi]$. This means beta is restricted in $[10^{-\varphi/10}, 10^{\varphi/10}]$. Hence the probability density function of β_u can be given by using simple transformation of random variable as

$$f(\beta_u) = \begin{cases} 0, & \beta_u < 10^{-\varphi/10} \\ \frac{2}{\ln(10)\varphi\beta_u}, & 10^{-\varphi/10} < \beta_u < 10^{\varphi/10} \\ 0, & \beta_u > 10^{\varphi/10} \end{cases} \quad (1)$$

where $ln(.)$ is the natural logarithm. The noise variance uncertainty (which follows Eqn. (1)) is included during signal generation for the decision test that can be seen in Figure.1.

A. Sensing algorithm based on HFD of spectral estimates

To compute the roughness, we consider HFD which is computationally less intense and can asses using only few samples. In this method, we construct k_n time series from the spectral estimates of fixed cyclic frequency ($S_r^{\alpha_d}(n, f)$) via sub-channels. The cyclic spectrum estimation of received signal can be formulated as [14]

$$S_r^{\alpha_c}(n, f) = \frac{1}{2N+1} \sum_{n=-N}^{N} \frac{1}{T} R_T(n, f + \frac{\alpha_c}{2}).R_T^*(n, f - \frac{\alpha_c}{2}), \quad (2)$$

where $R_T(n, f + \frac{\alpha_c}{2})$, $R_T^*(n, f - \frac{\alpha_c}{2})$ are the complex envelops of narrowband, and band pass components of the signal $r(n)$. These can be expressed as

$$R_T(n, f) = \sum_{k=-N'/2}^{N'/2} a(k)x(n-k)e^{-j2\pi f(n-k)T_s}$$

$$R_T^*(n, f) = \sum_{k=-N'/2}^{N'/2} a(k)y(n-k)e^{-j2\pi f(n-k)T_s}$$

Here $a(k)$ is a data tapering window of length $T = N'Ts$ seconds and the sampling period is Ts, N' is the number of points in the discrete FFT, k is the frequency (discrete). And the '$*$' denotes the complex conjugate, α_c is the frequency separation or cyclic frequency. N is the total number of discrete samples in the observed frame. Eventually, spectral estimates ($S_r^{\alpha_d}(n, f)$) is calculated using Eqn. (2) at desired CF whose index is estimated as $(Ceil(length(\alpha_c)/2))$.

Figure 1 shows the complete block diagram of proposed spectrum sensing method based on fractal dimension of spectral estimates under noise variance uncertainty. In this model the noise added to the PU signal have uncertain and it can take the random values whose distribution is uniform. Then, the spectral estimates are computed using FFT accumulation method at one particular cyclic frequencies (CF). The roughness of the spectrum is evaluated using HFD method and compared with a pre-defined threshold to make the decision about PU signal presence.

For i^{th} sub-channel signal with N samples, the constructed series can be expressed as [15]

$$x_{i,m}^{k_n} = \{y_i(m), y_i(m+k_n), ..., y_i(m+\psi.k_n)\}, \quad (3)$$

where $\psi = \frac{N-m}{k_n}$, k_n is an integer (called as scale size), and $m = 1, 2, 3, .., k_n$. The length of sub-series can be defined as:

$$L_{i,m}(k_n) = \frac{(N-1)\sum_{j=1}^{\varphi} |x(m+jk_n) - x(m+(j-1)k_n)|}{k_n \lfloor (N-M)/k_n \rfloor} \quad (4)$$

Then, we average $L_{i,m}(k_n)$ over m to obtain $L_i(k_n)$ and calculate logarithm of $L_i(k_n)$ for $1 < k_n < k_n\max$. The logarithm of $L_i(k_n)$ will depend on k_n in the following form.

$$\log(L_i(k_n)) = H_{fd}.\log(1/k_n) \quad (5)$$

where H_{fd} is an estimated fractal dimension. This measure can be used as a measure of complexity to sense the spectrum. Hence, in this work, we consider it as a test statistic to discriminate the hypotheses. Mathematically, the decision statistics to sense the frequency band is given as $H_1 : H_{fd} > \lambda_{fd}$ or $H_0 : H_{fd} \leq \lambda_{fd}$.

where λ_{fd} is the pre-defined detection threshold which depends on estimated fractal dimension of spectral estimates of white Gaussian noise of length N and probability of false alarm (P_f).

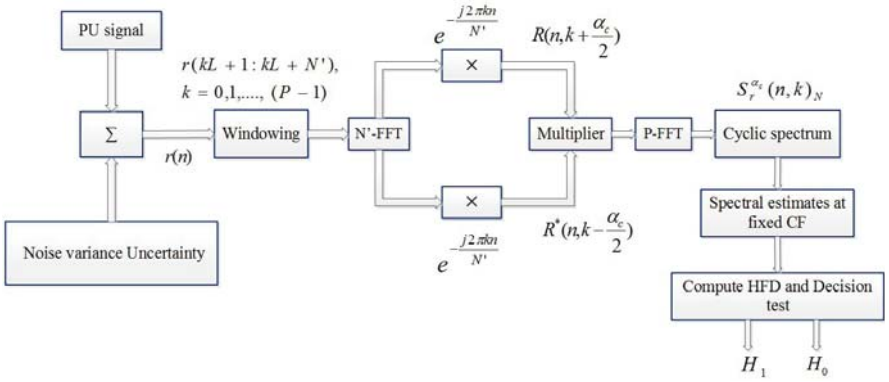

Fig. 1. Proposed sensing method based on fractal dimension of spectral estimates under noise uncertainty

III. Cooperative sensing using DS theory

In cooperative sensing, numerous fusion methods have been proposed to improve the sensing performance [16]. Among those methods, hard decision fusion techniques such as AND, OR, and MOST rules are commonly used to analyze the detector performance. Cooperative/cumulative detection probability (Q_d) of AND, OR, and MOST logics are given as [17]

$$Q_{\text{d-AND}} = \prod_{m=1}^{M} P_{d,m}, \tag{6}$$

$$Q_{d-OR} = 1 - \prod_{m=1}^{M} (1 - P_{d,m}), \tag{7}$$

$$Q_{d-MOST} = \sum_{m=n_d}^{M} \begin{pmatrix} M \\ m \end{pmatrix} P_{d,m}(1 - P_{d,m})^{M-m}, \tag{8}$$

where ($P_{d,m}$) and ($P_{f,m}$) are the detection and false alarm probability of m^{th} CR user, n_d is an integer representing decision threshold for most logic and its value is $n_d \geq M/2$, and $\begin{pmatrix} M \\ m \end{pmatrix} = {}^{M}C_m$ is a factorial function.

IV. Simulation results

In this section, we present our numerical results to describe the performance of energy detection and proposed detection method and effect of noise uncertainty on it. Quadrature Phase Shift Keying (QPSK) signal with variable SNR are considered as a PU signal. The noise uncertainty is modeled as uniform distribution. We model the fact that there is at most 'x'dB of uncertainty in the noise processes. In practical applications, the upper bound on noise uncertainty factor can be taken below 2dB [18]. The noise variance uncertainty is introduced during test which is fixed random value for one iteration and varies in each iteration in such a way that the distribution of noise uncertainty for all the iterations follows an uniform distribution. The sample length is taken as 256. In the case of energy detection, the threshold is pre-computed with noise variance one and for to achieve a tolerable (as per cognitive radio standard) false alarm probability. In the case of proposed method, the performance is evaluated based on estimated fractal dimension of spectral estimates at one particular cyclic frequency. The desired CF is evaluated as $(Ceil(length(\alpha_c)/2))$. Threshold evaluation of the proposed method depends on estimated fractal dimension of spectral estimates with noise alone in the received signal and probability of false alarm (P_f=0.1). The detection probability is estimated based on Monte Carlo simulations of 1000 iterations that mean the solutions are approximated to three decimal places. The snapshot/frame based method is considered for detecting a signal in the desired frequency band to be scanned. We extended the work to the cooperative sensing which use hard decision fusion techniques to make global decision. Number of nodes considered in cooperative network is a variable and taken up to 5. The performance of both sensing methods is presented signal strength against detection probability. Evaluation of detector performance is observed based on SNR vs. detection probability curves.

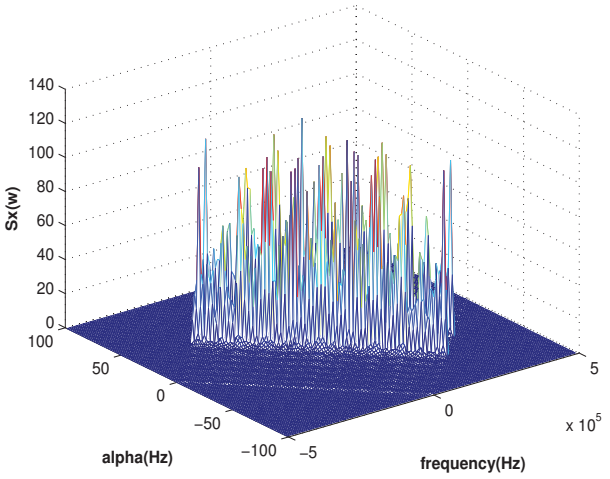

Fig. 2. Spectral estimates of WGN with different cyclic frequencies

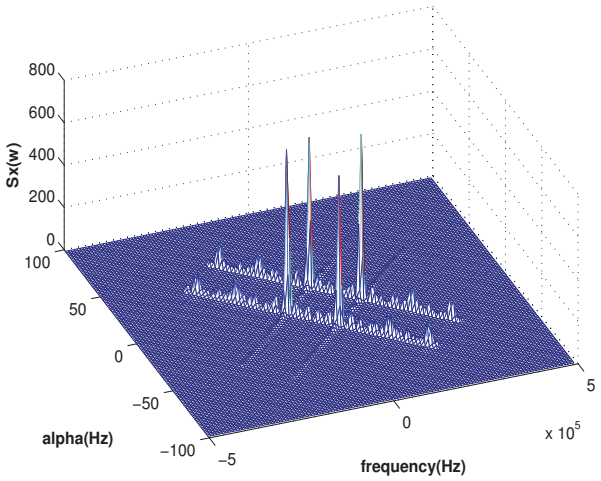

Fig. 3. Cyclic spectrum of received signal at SNR = 5dB, QPSK, N = 256

Figures 2 and 3 represents the cyclic spectrum of received signal with PU signal active and inactive at a particular frequency band, respectively. We considered rectangular windowing function to select the frame of samples. The uncertainty factor value is randomly taken within the considered range. From the figure, it can be seen that, cyclic spectrum has peaks at cyclic frequencies when the PU signal is present in the received sequence where as there is no significant peaks observable in noise (without PU signal in the channel).

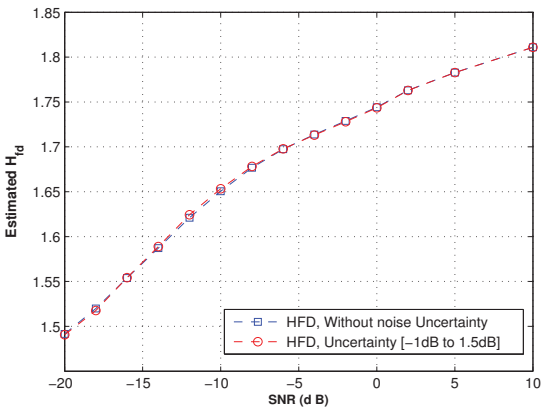

Fig. 4. Fractal dimension of spectral estimates at fixed cyclic frequency with variable SNR

Figure 4 represents fractal dimension of spectral estimates at one particular CF of received signal with different signal strength (varied from -20dB to 10dB). In the simulation, we have considered the K_n values from 4 to 10 and averaged their fractal dimension measure to improve the accuracy of the estimated HFD value. Where K_n is a number of sub-series composed from the received signal. From the figure, it is clear that the roughness of the spectrum increases as the signal-to-noise ratio of the signal increases. Hence, fractal dimension measure can be used one of the method to sense the PU signal in the band to be scanned.

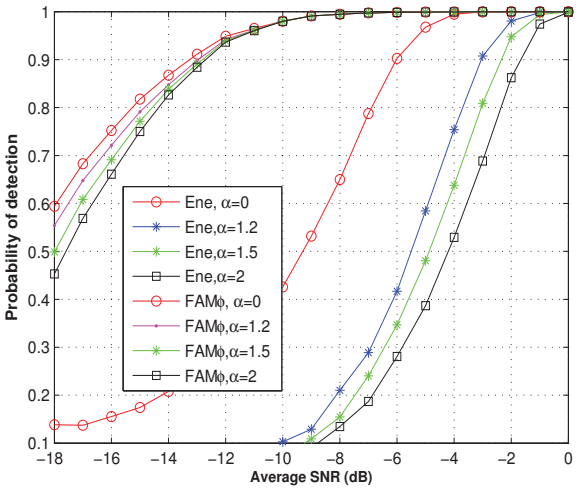

Fig. 5. Performance of proposed and energy detectors under noise variance uncertainty

Figure 5 shows the performance (SNR vs. P_d) of proposed and energy detector under various noise uncertainty factor (β_u=0.1, 1.2, 1.5, and 2). The signal strength is varied from -18dB to 0dB, N=256, and P_f=0.1. As the uncertainty increases, energy detector performance reduces significantly at all signal strengths. However, the proposed method namely fractal dimension of spectral estimates detector is less sensitive to noise variance uncertainty and its effect is negligible up to -12dB. From the figure 5, it can be seen that, the proposed detector is robust against noise variance uncertainty and is able to detect the weak signals up to -13dB as per the cognitive radio standards with respect to sensing parameters (P_d=0.9 and P_f=0.1). In contrast, the energy detector is able to detect the signal of SNR up to -6dB and and its performance further degraded with increase in uncertainty factor.

Figure 6 represents signal strength against detection probability curves with different number of CR nodes in cooperation using logical AND, OR and MOST for proposed sensing method. We considered two cognitive radio cooperative networks, one is with three nodes and the other one with five nodes. From the figure it can be observed that, detection probability increases as the number of nodes increases except for OR, which can be expected based on their logic. In addition, A close observation of these figures show that OR fusion rule gives better P_d for same P_f compared to other fusion rules (AND and MOST). Though the performance of the MOST logic is less than the OR decision, we considered because of its reliability to make the global decision. This is owing to the fact that one malicious decision can change the entire cooperative decision using OR and AND fusion logic.

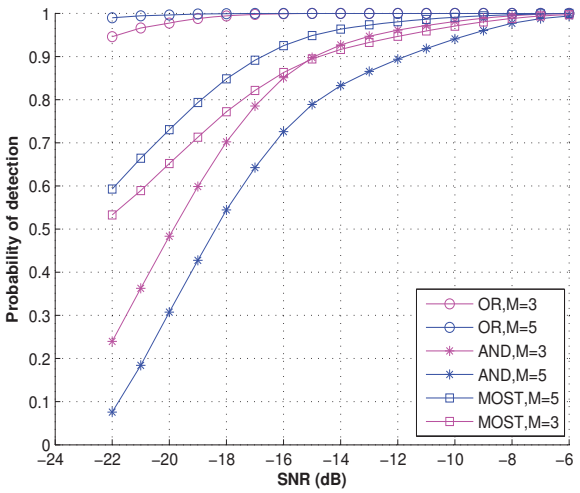

Fig. 6. Performance of proposed cooperative sensing with different hard decision fusion logic

V. Conclusions

In this work, we proposed and analyzed fractal dimension of spectral estimates sensing method under noise variance uncertainty. The notion of using the method is the fact that the fractal dimension of spectral estimates of the PU signal embedded with noise is high compared to fractal dimension of spectral estimates with noise alone. Moreover, its complexity varies as we vary the signal strength. From the simulation results, proposed method is shown to be less sensitive to noise variance uncertainty, whereas the energy detector completely depends on noise variations in the signal. The cumulative detection probability based on hard decision fusion method increases with number of nodes except for AND logic as expected. In conclusion, proposed method is robust against noise variance uncertainty up to -13dB. It shows approximately 7dB performance improvement at desired sensing probabilities, which is a significant performance improvement for cognitive radio systems. As a future work, one can improve the proposed sensing performance by selecting the optimal fractal dimension measure.

***Abstract*—Spectrum sensing is a primary function in cognitive radio (CR) to improve radio spectrum utilization by dynamically accessing unused frequency bands while causing no interference to licensed users. In literature, many of the works considered that the noise distribution is Gaussian under assumption that the sample size is infinity to make the detector threshold. But, in real time available size of sample data at the cognitive radio to sense the spectrum is limited. Moreover, it should be as low as possible to reduce the computation complexity. Due to fixed threshold design based on prior assumption of Gaussian noise leads to unreliable spectrum decision, particularly, in low signal-to-noise ratio (SNR) environment. However, selection of appropriate detection method and framing an adaptive threshold with finite data are important to improve the detection performance of CR system. To address the above problems empirical permutation entropy (ePEn) detector with adaptive thresholding (EPEAT) method is introduced for cognitive radio system. Simulation results indicate that the proposed method is less sensitive to sample size, independent of bin width, and the dynamic thresholding according to available samples can improve the detection performance.**

I. Introduction

One of the key challenges of cognitive radio (CR) is to detect the presence or absence of the signal in a desired frequency band at low signal-to-noise ratio (SNR) with the constraint that it should not interfere with the primary user (PU) [1]. To achieve this, quite a few signal detection methods have been proposed over the years, such as energy detection, entropy detection, cyclostationary detection, eigen-value based detection, covariance based detection, and interference based detection etc.[1]. Each one of these has their own advantages and disadvantages. There are several fusion methods for co-operation spectrum sensing to improve detection performance. But, the most important process before applying fusion technique is the framing/selection of adaptive threshold for local sensing according to the distribution of available/finite samples of signal data at each sensor.

In recent past, a number of different entropy estimators have been applied in biomedical applications, meteorology, physics, statistical time series analyses, nonlinear dynamics, and economics applications to quantify the complexity of signals [2], [3]. Different entropy techniques are presented to predict the PU signal status for cognitive radio applications [4], [5], [6]. However, the authors have not consider the effect of sample size on the performance of the detectors. In addition, many of the above entropy detectors consider fixed bin width and finite number of samples which gives unreliable decision, i.e., inefficient estimation of probability distribution of received sample data during entropy estimation. This is due to distribution of data that might be sparse in the tails and more numerous in the middle. Entropy of a discrete time series can be calculated either from direct time sequence (called as embedding entropy) or from frequency domain of it (called as spectral entropy). In this work, advanced embedded entropy method such as empirical permutation entropy (ePEn) is studied and analysed their performance using small data sets to predict the signal status in low SNR regime. The motivation to consider the empirical permutation entropy is due to its ability to predict the discrete time series data periodicity with finite data and its independent property of bin width assumption.

In fact, real time statistical behavior of the received data at CR differs from the Gaussian approximation because not only due to channel noise uncertainty but also due to incomplete/finite sample of data available for test [7]. The effect of estimated noise variance using finite sample of data and deviation of true noise variance from population is given in [7]. To address the effect of limited sample data on sensing performance, one can choose an appropriate signal detection technique and make the threshold adaptive based on available data. In practice, high threshold value causes interference to the PU signal because the detector unable to detect the presence of PU signal. In contrast, low threshold value causes inefficient spectrum utilization by CR users even when opportunities are present. This is due to detector inability to detect the PU signal. There has been several research works in determining methods that select detection threshold with assumption of Gaussian noise distribution [8]. A double threshold technique to improve global decision in a cooperative spectrum sensing scheme is presented in [8]. The results show that this method improves decision making at the fusion centre, however, the authors do not address the problem of how to determine individual thresholds with finite sample size. Here, we design adaptive threshold based on noise variance of available finite data and analyses the performance using permutation entropy.

The focus of the current work is to detect the PU signal reliably in low SNR regime with finite sample of data available

at cognitive radio receiver. To achieve this, an empirical permutation entropy with adaptive thresholding (EPEAT) by estimating the noise variance based on nonparametric regression is introduced. We consider an algorithm which is shown as the best method for estimating noise variance with limited data using nonparametric regression [9]. To show the performance improvement of the proposed method, we consider spectral entropy, eigenvalue, and energy detection methods.

Rest of the paper is organized as follows. Section II presents proposed empirical permutation entropy with adaptive thresholding (EPEAT) technique as well as considered detection methods for comparative analyses. Simulation results are discussed in Section III. Finally, our conclusions are presented in Section IV.

II. Sensing algorithm

The objective of spectrum sensing is to discriminate between the following two hypotheses H_0 (PU signal is absent) and H_1 (PU signal is present) [10].

$$H_0 : r[i] = w[i], i = 0, 1, 2, \ldots, (N-1)$$
$$H_1 : r[i] = hs[i] + w[i],$$

where $r[i] = [r(0), r(1), r(2), \ldots, r(N-1)]$ is the received signal sequence received by the CR user, N is the incomplete sample of data or finite samples of signal received at sensor. The channel gain (h), transmitted signal $\mathbf{s}[i]$, and the additive white Gaussian noise (AWGN) $\mathbf{w}[i]$ with mean zero and variance σ^2 are independent of each other. We assumed that the channel is time invariant during the sensing period.

A. Detection algorithm based on Energy measurement

The test statistic for energy detector (ED) can be represented as [11]

$$\psi(r) = \sum_{i=0}^{N-1} |r[i]|^2 \underset{H0}{\overset{H1}{\gtrless}} \lambda_e, \tag{1}$$

where ψ is the energy of the received signal and (λ_e) is the threshold which depends up on the probability of false alarm P_f and number of samples.

B. Detection based on Spectral entropy

Spectral entropy is one of the measures of uncertainty using spectral properties of the received signal data. In this detection process, the spectral entropy of the received signal is estimated using the histogram method and is calculated by transforming the received signal of length N into the frequency domain [12], [5].

Thus, the entropy of frequency domain signal can be estimated as

$$SpEn = -\sum_{j=1}^{L} \frac{f_j}{N} \log_b \frac{f_j}{N} \tag{2}$$

where f_j denote the probability of samples fallen in each bin.

Based on the estimated entropy of receiving a signal and adaptive threshold (λ_ϕ) value, the detector decides H_0 : $SpEn > \lambda_\phi$ or $H_1 : SpEn \leq \lambda_\phi$.

C. Detection algorithm based on eigenvalues

In case of eigenvalue based spectrum sensing (maximum-minimum eigenvalue (MME) detection), the test statistics can be computed based on sample Covariance matrix of the received signal, can be given as [13]

$$R_r(N) \underline{\underline{def}} \frac{1}{N_s} \sum_{i=0}^{N-1} \mathbf{r}(i) \mathbf{r}(i)^\dagger, \tag{3}$$

where N is the number of collected samples and † is the Hermitian operator.

Let the ordered eigenvalues of the covariance matrix be the $\zeta_{\max} = \zeta_1 > .... > \zeta_i > ..... > \zeta_M = \zeta_{\min}$. Then, one can take the decision about PU activity in the desired frequency band based on maximum and minimum eigenvalue of the matrix $R_r(N)$, that is, $\zeta_{\max}$ and $\zeta_{\min}$. If $\zeta_{\max}/\zeta_{\min} > \lambda_{eig}$, signal exists in the band under scan. Otherwise, signal does not exist where λ_{eig} is a threshold, and is computed as

$$\lambda_{eig} = \frac{(\omega)^2}{\left(\sqrt{N} - \sqrt{ML}\right)^2} \cdot \left(1 + \frac{(\omega)^{-2/3}}{\left(N.ML^{1/6}\right)} F_1^{-1}(1 - P_f)\right) \tag{4}$$

where $\omega = (\sqrt{N} + \sqrt{ML})$, $F(.)$ is the probability density function of eigenvalues of covariance matrix with noise alone also called as Wishart random matrix.

D. Permutation entropy

Empirical permutation entropy (ePEn) was introduced to quantify complexity on the base of finite data sets [14]. It is based on the distributions of ordinal patterns, which describe order relations between the values of a discrete time series. On the one hand, permutation entropy is strongly related to Kolmogorov-sinai (KS) entropy [15]. It coincides with KS entropy for piecewise strictly monotone interval maps and is not less than KS entropy for many dynamical system. On the other hand, permutation entropy is estimated by empirical data, which is conceptually simple and algorithmically fast [16].

To calculate the ePEn of received signal $\{r(i), i = 1, 2, .., N\}$, which are embedded to an m-dimensional space can be given as

$$R_i = [r(i), r(i+l), .../r(i+(m-1)l)], \tag{5}$$

where m is the embedding dimension and l is the time lag. R_i is the i^{th} point in the m-dimensional space; $1 \leq i \leq N - (m-1)l$.

For R_i, the real values in above Eqn. (5) are arranged in an increasing order, so it can be written as follows:

$$R_i = [r(i + a_1.l) \leq r(i + a_2.l) \leq ... \leq r(i + a_m.l)]. \tag{6}$$

where $a_1 = (j_1 - 1)$. When an equality occurs, such as $r(i + (j_{n1} - 1)l) = r(i + (j_{n2} - 1)l)$, the two values $r(i + (j_{n1} - 1)l)$ and $r(i + (j_{n2} - 1)l)$ can be ordered by the values of their corresponding j. Namely, if $j_{n1} < j_{n2}$, then the order is $r(i + (j_{n2} - 1)l) \leq r(i + (j_{n1} - 1)l)$.

Hence, the vector X_i can be uniquely mapped onto: $\pi_i = [j_1, j_2, ..., j_m]$, where π_i is one of $m!$ possible permutations of m distinct symbols $(1, 2, ..., m)$.

If π_i is considered as a symbol, then all points in the m-dimensional embedding space can be expressed as a symbol sequence $\left[\pi_1, \pi_2, ..., \pi_{N-(m-1)l}\right]$. Hence, this procedure maps the original discrete time series onto a symbol sequence. The number of the distinct symbols can be most at $m!$.

Let the occurrence number of π in $\left[\pi_1, \pi_2, ..., \pi_{N-(m-1)l}\right]$ be k, then the occurrence probability of π is $k/\left(N-(m-1)\,l\right)$. Let the number of distinct symbols in $\left[\pi_1, \pi_2, ..., \pi_{N-(m-1)l}\right]$ be k, and the corresponding occurrence probabilities be $p_1, p_2, .., p_k$, then the ePEn of the discrete time series is calculated as [16]

$$H_p = -\sum_{j=1}^{k} p_j ln(p_j), \tag{7}$$

where H_p is the value of ePEn. The low values of ePEn indicate signal presence and high values of ePEn represent random noise. In practice, to detect the dynamical changes, the data is first partitioned into non-overlapping windows of suitable length. Mathematically, the decision statistics to sense the frequency band is given as $H_0 : H_p > \lambda_{pe}$ or $H_1 : H_p \leq \lambda_{pe}$.

The threshold (λ_{pe}) is calculated as.

$$\lambda_{pe} = H_{pw} + \Theta_s.(Q^{-1}(1 - P_f)) \tag{8}$$

where H_{pw} is the estimated empirical permutation entropy of standard Gaussian noise, Θ_s is the scaling parameter depends on estimated noise variance ($(\sigma_w^*)^2$) of received samples and its size (N), Q is the complementary distribution function of the standardized Gaussian.

To estimate the noise variance of received signal at CR, it is required to find the best estimate of $s[i]$. This can be achieved in two methods. One method is based on parametric regression and the another one is using nonparametric regression. The parametric regression requires a priori knowledge of the received signal in terms of an equation (also called as regression equation). But, signal data received at each cognitive radio, however, cannot be modeled/parameterized in terms of predetermined analytical function. Hence, nonparametric regression is considered and is usually the best method for estimating noise variance with considered length of sample data. To estimate the noise variance, we consider the model given by [9]. In this method, author used the fact that the model whose generalized cross validation (GCV) score is minimum can provide the standard deviation of additive white Gaussian noise.

III. Simulation results

In this section, we provide simulation results to evaluate the performance of the proposed EPEAT sensing algorithm, and compare it with that of spectral entropy detector, eigenvalue detector, and energy detector. Here, the meaning of incomplete is that the samples available for test in real time is finite. In the sequel, the desired probability of false alarm is fixed to 0.1. The two sets of finite sample size (512 and 256) of received signals at cognitive radio is taken to evaluate the sensing performance of considered detectors with proposed one . We consider a DVB-T signal which is a Matlab Simulink model that generates a signal with band width of 6MHz. The signals are sampled at a rate of 9.12 Msps. The implementation of empirical permutation entropy with adaptive threshold follows the procedure described in Section 2-D. Calculation of ePEn requires apriori values of delay (τ), embedding dimension (m), and the size of the sliding window (l). The value of m can be estimated using the calculation of false nearest neighbor algorithm. The use of sliding window is to get the permutation entropy trajectory of the captured discrete time series, which can be varied according to the application. In the simulation, we consider, τ=2, m=3, and the window size l is considered and varied between 5 to 15. The threshold for entropy detectors depends on estimated entropy of standard Gaussian noise of same length (N), desired P_f value, and the estimated standard deviation of noise using non parametric regression. In case of spectral entropy, the histogram of the received signal after FFT is evaluated based on number of bins L=15. In case of energy detection, the test statistic as per Eqn. (1) is evaluated and compared with the predetermined threshold (λ_e). In the case of eigenvalue based detector, we used tabulated values of Tracy-Widom (TW) distribution of order one due to complex nature of its function to make the threshold as per [13]. The sensing performance of each approach is quantified by the SNR versus detection probability. The detection probability is estimated based on Monte Carlo simulations of 10000 iterations that means the solutions are approximated to four decimal places. The snapshot/frame based method is considered for detecting a signal in the desired frequency band to be scanned [17].

Figures 1 and 2 illustrate the performance of spectral entropy detector and proposed permutation entropy detector with variable number of sample size (N = 256 and 512). From the figure, it can be seen that the entropy reduces as we increase the signal-to-noise ratio for both entropy detection methods. In addition, dependency of discriminate the PU signal on sample size is very less for entropy detection methods. Particularly, in the case of proposed detection method. The block color line indicates the entropy of standard white Gaussian noise of sample size equal to the signal length from which we can observe the sensing ability of considered entropy method.

Figure 3 represents the estimated ePEn values with different time lags (l) varied from 5 to 15. The sample length is considered as 256. From the figure, it can be seen that the estimated permutation entropy increase as we increase the l value. However, the ability to discriminate the signal from noise is same for all values of l. Hence, for further analyses, the least value in the considered range is taken, which is equal to 5.

Figure 4 shows the threshold values at different false alarm probabilities of proposed entropy detector with standard Gaussian random noise of length 256. In this simulation, threshold values are measured based on permutation entropy

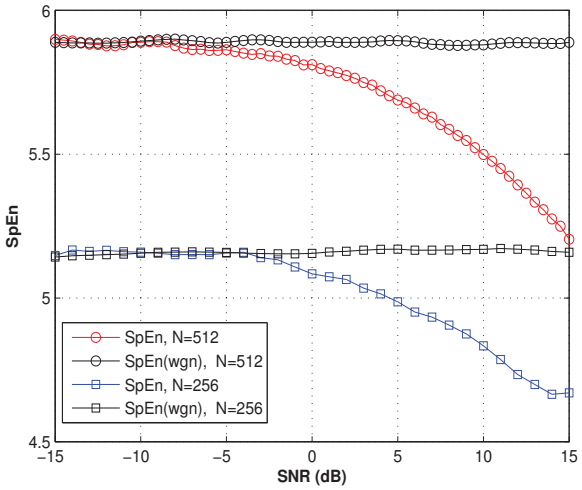

Fig. 1. Estimated entropy of captured signal and WGN using SpEn detector.

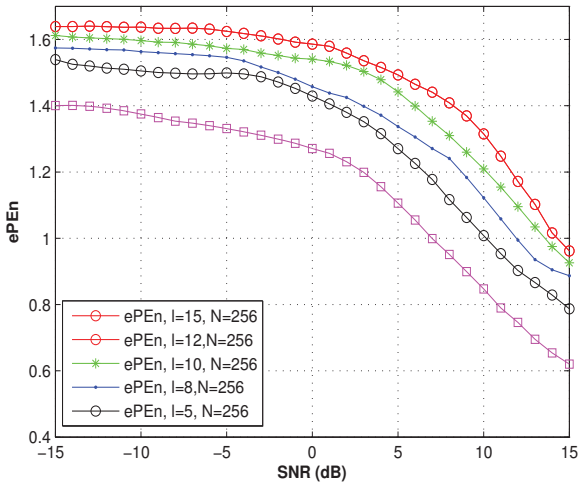

Fig. 3. Estimated entropy of captured signal and WGN using ePEn detector.

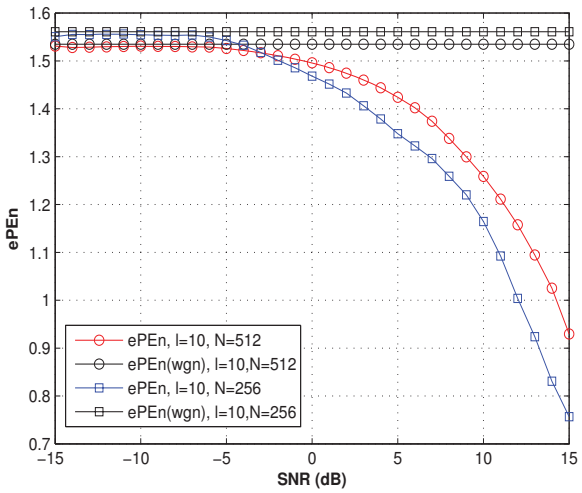

Fig. 2. Estimated entropy of captured signal and WGN using ePEn detector.

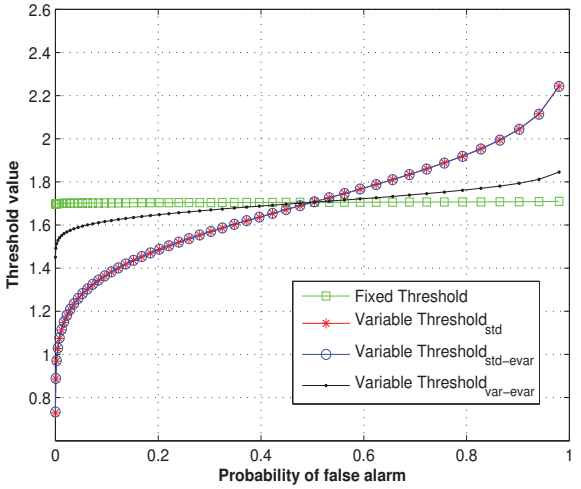

Fig. 4. Threshold value with fixed and estimated noise variance of proposed method for different P_f values

for different parameters namely fixed standard deviation, fixed variance, estimated standard deviation and estimated variance using nonparametric regression. From the figure, it can be seen that, in the case of fixed threshold detection, threshold is nearly constant for all values of false alarm probabilities. However, adaptive thresholding by estimating noise variance of the received signal vary significantly which is responsible to improve the detection probability of the detector (from P_f=0.5 to 0). From the results, threshold values are same with true standard deviation and estimated standard deviation of noise based on nonparametric regression. However, detection probability degrades compared to fixed threshold entropy detector at higher false alarm probability from 0.5 to 1. In practice, the desired values of P_f should be less than or equal to 0.1 (according to the IEEE 802.22 WRAN standard) which supports that the adaptive thresholding technique is more appropriate for real time applications of cognitive radio system.

Figure 5 illustrates the local sensing performance of proposed entropy detector with dynamic thresholding (EPEAT), spectral entropy detector with adaptive threshold, eigenvalue detector, and classical energy detector at different size of sample data (N=512 and 256). From the figure, it can be observed that the proposed EPEAT detector is less sensitive to sample size and shows its ability to predict the PU signal status even with incomplete sample of data. In general, entropy detectors have good discriminating ability with finite sample of data. However, based on the results, the proposed permutation entropy is less sensitive to sample size compared to spectral entropy detector. Moreover, the detection probability is re-

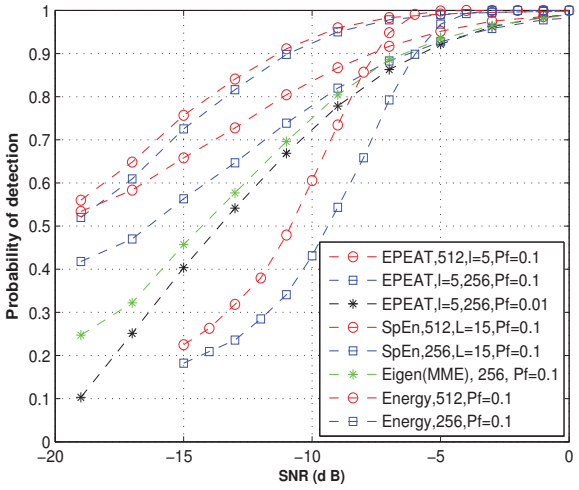

Fig. 5. Performance of EPEAT detector with considered detectors, N=256 and 512, P_f=0.1 and 0.01

duced as we reduce the false alarm probabilities from P_f=0.1 to 0.01. It can be seen that the detection probability increases as the signal strength at the sensor increases as expected. The EPEAT, eigenvalue, and spectral entropy detectors are able to detect noisy signal of SNR up to -12dB, -7dB, and -10dB, respectively with 90% accuracy. In contrast, the energy detection method is able to detect noisy signal up to -6dB using sample size of 256.

IV. Conclusions

In this work, we proposed and evaluated an empirical permutation entropy with adaptive thresholding (EPEAT) method by estimating the noise variance of the received signal using nonparametric regression. It can estimate the noise variance in the received signal with accuracy of 95% and requires no prior knowledge of the primary user signal and noise distribution. The accuracy of the estimated variance can be increased with the increase of sample size. The experimental results show that the proposed method has better performance especially with finite sample size of signal in low SNR environment. In particular, the proposed EPEAT method is shown to be less sensitive to variable sample size, whereas the energy detector completely depends on sample size available at sensor. Moreover, proposed method with variable threshold can detect the signal of SNR up to -12dB with sample size of 256. In conclusion, the detection method outperforms the recent method namely spectral entropy, eigenvalue, and energy detectors by 2dB, 5dB, and 6dB respectively, which is a significant improvement for local sensing in cognitive radio systems. The cooperative sensing with adaptive thresholding technique over fading environment is under development to improve detection performance.

***Abstract*— In this paper, an improved decoder structure on previously proposed multicarrier-code division multiple access (MC-CDMA) watermarking is proposed. To simulate attack channel, Rayleigh distribution along with the additive white Gaussian noise (AWGN) is considered. We mathematically show that the proposed decoder structure incorporates the effect of fading attack unlike the widely used correlator decoder. The concept of multiuser detection (MUD) principle which is widely used in CDMA is then explored to cancel the effect of multiple bit interference (MBI). Two variants of combined interference cancelation (CIC), namely threshold combined interference cancelation (TCIC) and group combined interference cancelation (GCIC) are then developed. Mathematical analysis with simulation results show that TCIC does not offer any bit error rate (BER) performance gain relative to CIC, while a significant improvement in BER performance and watermark payload are achieved through GCIC.**

Index words-Multicarrier code division multiple access, spread spectrum watermark, MMSEC decoder, CIC,TCIC, GCIC

I. Introduction

Spread spectrum (SS) watermarking has found to be efficient for imperceptible, robust and cryptographically secured data hiding scheme on digital media [1][2]. Despite the advantages of blind detection and robustness, its suffers from host signal interference (HSI), payload problem and poor detection for corrlator in presence of random gain operation [3]. Perceptually adaptive multi-carrier (MC)-SS is reported in [4] with minimum mean square error combining (MMSEC) decoder to design robust system against gain attack. Improved detection scheme based on statistical decision rules with probability density function [5] and multiplicative [6] SS watermarking are also reported. To increase payload, the concept of modified M-ary watermark decoding algorithm using a tree-structure with the number of correlators equal to $2log_2M$ [7] and code division multiple access (CDMA) are used [8].

In [3], [4], a MC version of SS watermarking on digital images is proposed. The host/cover image is decomposed into N-mutually orthogonal signal points and each watermark bit is embedded using a distinct code pattern. Decision variable for the embedded watermark bit is formed from the weighted average of N-decision statistics applying MMSEC strategy. We extend here this work for embedding a set of binary watermark bits using a set of orthogonal code patterns and call it MC-CDMA watermark. MC-CDMA watermarks suffer from multiple-bit interference (MBI) effect. Two variants of combined interference cancelation (CIC), namely threshold interference cancelation (TCIC) and group combined interference cancelation (GCIC) are then developed. Simulation results show that GCIC scheme offers significant gain in bit error rate (BER) for watermark decoding and consequently improved watermark payload/capacity is achieved relative to CIC and TCIC. Simulation results also show that iterative interference cancelation offers further improvement in BER subject to the relative gain achieved at initial stages.

The rest of the paper is organized as follows: Section II describes system model for MC-CDMA watermarking. Section III describes detection improvement through interference cancelation. Section IV presents performance evaluation while conclusions are drawn in Section V.

II. MC-CDMA Watermarking

Let us assume that the host signal $\mathbf{X}$ is decomposed onto N-mutually orthogonal signal points, where each signal point corresponds to a vector or signal in N-dimensional signal space. Let us also assume that the watermark is a binary valued signal i.e. $\mathbf{W} = \{b_1, b_2, b_3, ..., b_K\}$, where $b_i \epsilon \{1, -1\}$ and $i = 1, 2, ...K$. In MC-CDMA watermarking, each watermark bit is spread over N-signal points by adding each host signal point with an element of the respective bit's code pattern. Here, we consider a binary valued Walsh codes for SS watermarking. Fig. 1 shows the block diagram representation of the proposed MC-CDMA watermarking model for k-th bit embedding along with attack channel modeled as Rayleigh distribution with additive white Gaussian noise (AWGN). The watermarked signal ($X^{'}$) [3] can be written as

$$X^{'} = (X_1 \pm \sum_k \gamma P_1^k) + (X_2 \pm \sum_k \gamma P_2^k) + ... + (X_N \pm \sum_k \gamma P_n^k) = \sum_{k=1}^{K} \sum_{n=1}^{N} X_n \pm \gamma . P_n^k \quad (1)$$

where $n, k \in z$ and γ is the embedding strength for additive SS. The symbol P_n^k corresponds to the n-th binary element of the k-th code pattern. The symbol $\pm$ indicates antipodal embedding, i.e. if '+' is used for embedding '1', '-' for '-1'.

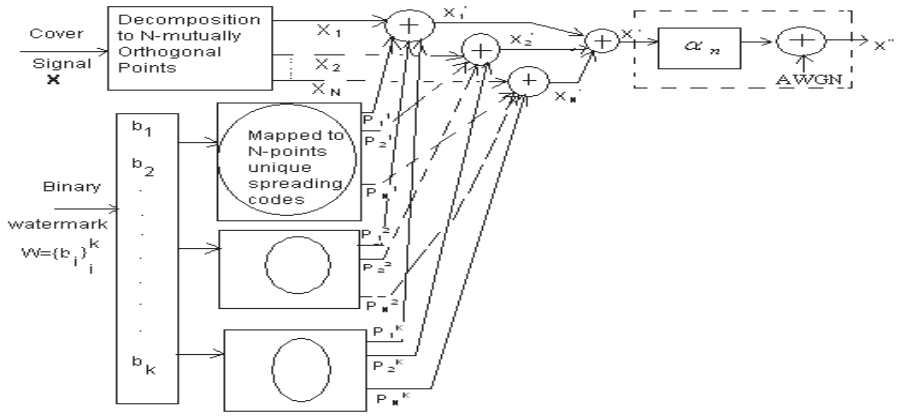

Fig. 1. MC-CDMA watermarking for k-th bit embedding

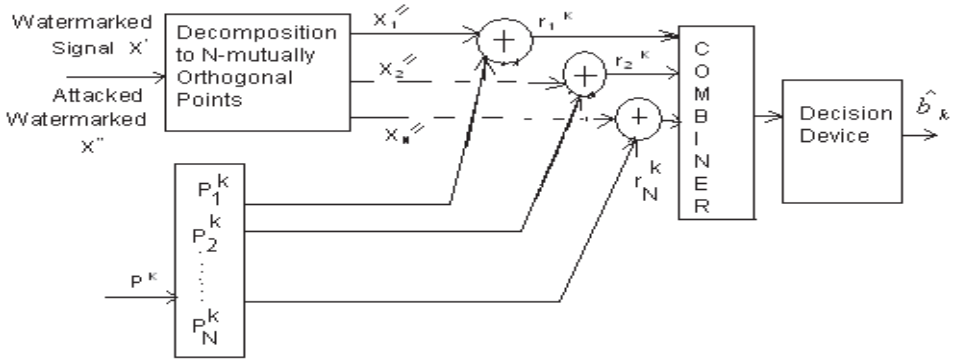

Fig. 2. MC-CDMA model of decoding for k-th watermark bit

Fig. 2 shows the block diagram representation of the k-th bit SS watermark decoding. We assume here that the watermark extraction/decoding is done with perfect synchronization. The received watermarked signal is first projected onto N-orthogonal signal points and is then correlated using j-th spreading (for decoding of j-th watermark bit) code that results in $r^j = (r_1^j, r_1^j, ...r_N^j)$ [3]. The decision variable for the j-th bit at n-th signal point is denoted by r_n^j and can be written as follows:

$$\begin{aligned} r_n^j &= < X_n^{''}, P_{nj} > \\ &= < P_{nj}, \sum_{k=1}^{K}\sum_{n=1}^{N} \alpha_n(X_n \pm \gamma.P_{nk}) + \eta_n > \\ &= \pm\alpha_n.\gamma \pm \sum_{k=1,k\neq j}^{K} \alpha_n.\gamma.\rho_{kj} + \eta_j \end{aligned} \quad (2)$$

where η_j is a Gaussian random variable with mean 0 and variance $N_0/2$. The symbol ρ_{kj} indicates the cross-correlation value due to the $j-$th and $k-$th code patterns. The expression of (2) is obtained assuming that the inner product of P_{nj} and X_n is zero i.e. HSI is assumed to be zero. The first term of (2) results in the auto-correlation value of j-th code pattern with zero lag, the second term is the sum of cross-correlation values among the different combinations of code patterns (except j-th code) and the third term is the AWGN noise component spread by j-th code pattern. The second term is called multiple bit interference (MBI) effect.

The decision variable D^j for the j-th bit obtained by MMSEC strategy [4] is

$$D^j = \sum_{n=1}^{N} r_n^j w_{nj} \quad (3)$$

where $w_{nj} = \frac{\alpha_n}{(\alpha_n^2\gamma^2\sum_{j=1}^{k} var(b_k)\rho_{kj}^2 + N_0/2)}$ and $var(b_k) = 1$. If knowledge of α_n not known, w_{nj} is calculated as in [4]. Substituting the value of the weight factors, the expression of the decision variable D^j for the j-th bit becomes

$$D^j = \sum_{n=1}^{N} \frac{\alpha_n}{\alpha_n^2\gamma^2\sum_{j=1}^{K}(var(b_k)\rho_{(kj)}^2 + N_0/2)} r_n^j \quad (4)$$

The decision variable D^j is fed to the decision device, the output of which determines the binary watermark bit pattern. Thus the correlator's outputs generate a decision vector $\mathbf{D} = [D^1 D^2 ....D^K]$ which is used to obtain an initial estimates of the embedded bits $\hat{b} = (\hat{b}_1, \hat{b}_2, \hat{b}_3, ...\hat{b}_K)$. These initial estimates are then used to evaluate the MBI.

III. Detection improvement through interference cancelation

MBI as shown in the second term in (2) greatly affects the detection performance at high payload. Analogous to

multiuser detection (MUD) in CDMA [9], nonlinear decision driven interference cancelation (IC) in watermarking can be categorized in two types- we call them here as (i) independent interference cancelation (IIC), where interference due to only one embedded bit is canceled at a time, and (ii) combined interference cancelation (CIC), where during detection of a particular watermark bit, interference due to all other group of watermark bits are estimated and canceled in one shot. While IIC takes much longer time for watermark detection to complete, CIC is attractive due to its fast speed through parallel processing but requires larger computation power. Moreover, performance improvement in CIC depends on the precise estimation of interference due to other watermark bits that leads to the relative gain achieved in interference cancelation. We briefly describe now CIC scheme along with its two variants, namely TCIC and GCIC, respectively.

A. Combined Interference Cancelation

Fig.3 shows the block diagram representation of j-th watermark detection using CIC scheme. The interfering effect, due to all embedded bits except the j-th bits, is removed to regenerate the watermarked signal containing j-th watermark bit only. The expression for this signal can be written as

$$X_j^{''} = X^{''} - \sum_{k=1, j\neq k}^{K} I_k \tag{5}$$

where I_k denotes the interference due to k-th watermark bit. This $X_j^{''}$ is then fed to the MMSEC decoder. The weights are then updated using interference cancelation as follows:

$$w_n^j = \frac{\alpha_n}{(var(b_k - \hat{b}_k)\alpha_n^2\gamma^2 \sum_{k=1}^{K} \rho_{(kj)}^2 + N_0/2)} \tag{6}$$

The weights in (6) can be calculated in two ways depending on the knowledge about the reliability of estimations.
(1) If the estimations are assumed to be correct, $var(b_k - \hat{b}_k) = var(b_k - b_k) = 0$,$\forall k \neq j$.
(2) On the other hand, if no knowledge about the reliability of the estimation for the watermark detected bits is available, $var(b_k - \hat{b}_k) = var(b_k - b_k) = 2$,$\forall k \neq j$. This value is due to the variation in the respective binary watermark embedding and decoding, thus $var(b_k - \hat{b}_k)$ as a discrete random variable with permissible possible values of 2, 0 and -2.

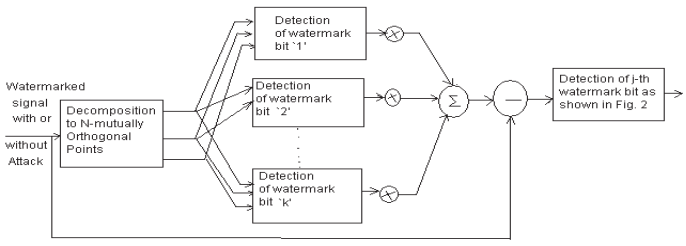

Fig. 3. CIC-SS watermark decoding for j-th watermark bit

B. Threshold combined interference cancelation

The flowchart for the implementation of TCIC watermark decoding algorithm is shown in Fig. 4. The decision variables for all the embedded watermark bits are first normalized. The normalized decision magnitudes above a specified threshold value (calculated from the conditional probability density function for a given P_e value) are assumed to belong to strong watermark bits. The expression of the normalized decision statistics for the j-th watermark bit is defined as

$$\begin{aligned} y_j &= \frac{D^j}{\sum_{n=1}^{N} \alpha_n w_n^j} = \frac{\sum_{n=1}^{N} r_n^j w_n^j}{\sum_{n=1}^{N} \alpha_n w_n^j} \\ &= \frac{\sum_{n=1}^{N} (\pm\alpha_n\gamma \pm \sum_{k=1,k\neq j} \alpha_n\gamma\rho_{kj} + \eta_j) w_n^j}{\sum_{n=1}^{N} \alpha_n w_n^j} \\ &= \pm\gamma \pm \frac{\sum_{n=1}^{N}\sum_{k=1}^{K} \alpha_n\gamma\rho_{kj}}{\sum_{n=1}^{N} \alpha_n w_n^j} + \frac{\sum_{n=1}^{N} \eta_j w_n^j}{\sum_{n=1}^{N} \alpha_n w_n^j} \end{aligned} \tag{7}$$

where $j = 1, 2, ...K$.

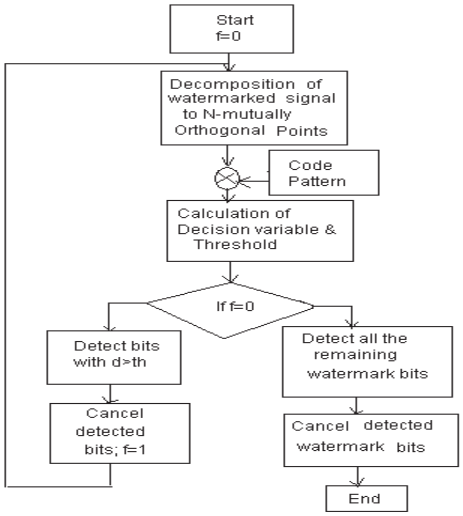

Fig. 4. TCIC algorithm for watermark decoding

If the number of embedded watermark bits are large enough (which is quite true for high payload system), the distribution of MBI i.e. the second term of (7) is Gaussian, and the third term is due to AWGN. So the total interference power is the sum of the variances of the second and the third terms in (7). Probability of bit error i.e. P_e in watermark detection can be calculated from the probability density function. The conditional probability density functions of the normalized decision statistics y_j for the given $b_j = 1$ and $b_j = -1$ are Gaussian centered at $+\gamma$ and $-\gamma$, respectively. This is symmetric in nature and the analysis can be simplified to consider only the positive values of y_j. Using Bayes rule, the

conditional probability of error is

$$P_e = P_e[b_j \neq 1/y_j] = \frac{P_e(y_j/b_j = -1)}{P(y_j/b_j = 1) + P(y_j/b_j = -1)} = \frac{1}{1 + exp^{(2y_j/\sigma_j^2)}} \quad (8)$$

The threshold value for the normalized decision statistics to determine the strong watermark group (9) as

$$Y_{th}^j = \frac{\sigma_j^2}{2} log[\frac{1 - P_e}{P_e}] \quad (9)$$

IC may sometimes cause degradation in detection performance. This is due to the inaccurate estimation of interference and its subsequent cancelation leads to further increase in interference power (i.e. variance). In the first iteration, the watermark bits with normalized decision statistics greater than the threshold are detected directly using MMSEC decoder without IC. Interference due to these watermark bits is then removed from the watermarked signal and the rest watermark bits are detected. The estimated data thus obtained for each strong watermark bit is used to cancel the interfering effect in the next iteration. Now, the normalized decision statistics of all the watermark bits are compared with the threshold and the strong bits are detected directly using MMSEC decoder. This estimated data is then used to calculate interference due to the strong bits, remove this effect from the watermarked signal and the weak bits are then detected. This process is repeated iteratively until a desired probability of error is achieved or a pre-set number of iterations are complete.

C. Group combined interference cancelation

The flowchart for the implementation GCIC is shown in Fig. 5. Here the decision magnitudes are sorted in desending order. The embedded watermark bits are then partitioned into different groups based on the magnitudes of decision statistics. In the present analysis, the watermark bits are partitioned into two groups, namely the strong and the weak watermark groups. Now, CIC is performed within the group of strong watermark bits by simultaneously canceling the interference of all other watermark bits except the desired one and the strong watermark data bits are thus estimated. Using the updated data of strong watermark bits, the interference due to these bits are removed and CIC is employed within the group of weak watermark bits. The weak watermark bits are then estimated. In the subsequent iterations, the interference experienced by each watermark bit is canceled based on the estimated data from the previous iteration. Now, all the decision magnitudes are again arranged in descending order and GCIC process is repeated iteratively until a desired probability of error is achieved or a preset number of iterations are completed.

IV. Performance Evaluation

This section presents BER performance of the proposed MC-CDMA watermarking for CIC, TCIC and GCIC schemes. Fig. 6(a)-(b) show the cover images of sizes (256×256), 8 bits/pixel, Fig. 6(c) is a binary watermark of size (32×32)

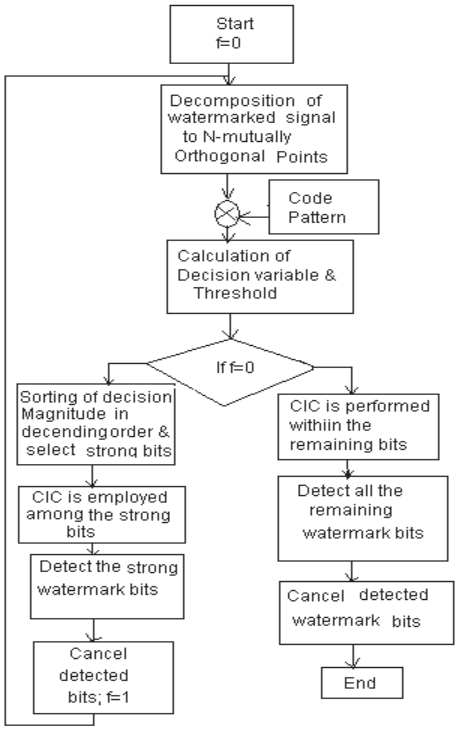

Fig. 5. GCIC algorithm for watermark decoding

and Fig.6 (d)-(e) show the watermarked images. The values for peak-signal-to-noise ratio (PSNR) and structural similarity index measure (SSIM) are $\sim 40dB$ and ~ 0.98, respectively. Fig. 7(a) shows detection performance vs watermark-to-noise ratio (WNR) for the proposed MC-CDMA watermarking using CIC, TCIC and GCIC schemes after 1st iteration (i.e after 1st stage IC). WNR is the ratio of watermark power-to-noise power, noise considered here as AWGN with zero mean and some variance. The value of probability of watermark bit detection error (P_e) is set at 10^{-2} while calculating the threshold for TCIC scheme. It is clear from Fig. 7(a) that GCIC significantly improves BER performance compared to CIC and 5dB off from MC-CDMA watermarking at a BER of 10^{-3}[8]. At low WNR, TCIC performs almost similar to MC-CDMA watermark detection without IC. This is because very few decoded watermark bits have decision values that exceed the threshold value and can be treated as strong embedded bits. On the other hand, performance of TCIC is improved with the increase in WNR. Fig. 7(b) shows performance of the MC-CDMA watermarking for the three different IC schemes at the end of 2 iterations i.e. 2nd stage IC. As expected, all three IC methods offer significant performance improvement. GCIC performance is 3.5 dB off MC-CDMA watermark performance at a BER of 10^{-3}[8]. A gain of 2dB is achieved with GCIC relative to conventional CIC at a BER of 10^{-2}.

Fig. 7(a) and Fig. 7(b) also show the effectiveness of calculating the weights in MMSEC as shown in Section III A. W1 is the weight considering the estimation is assumed to be correct, while W2 corresponds to the weight when no knowledge about the reliability of the estimation for the watermark decoded bits

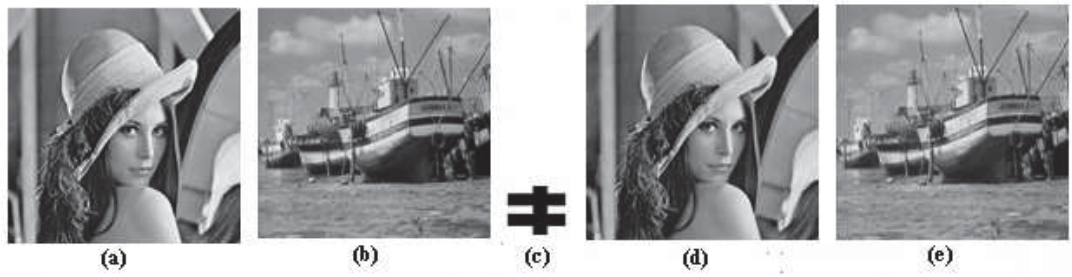

Fig. 6. (a)-(b) cover image , (c) binary watermark, (d)-(e) watermarked image

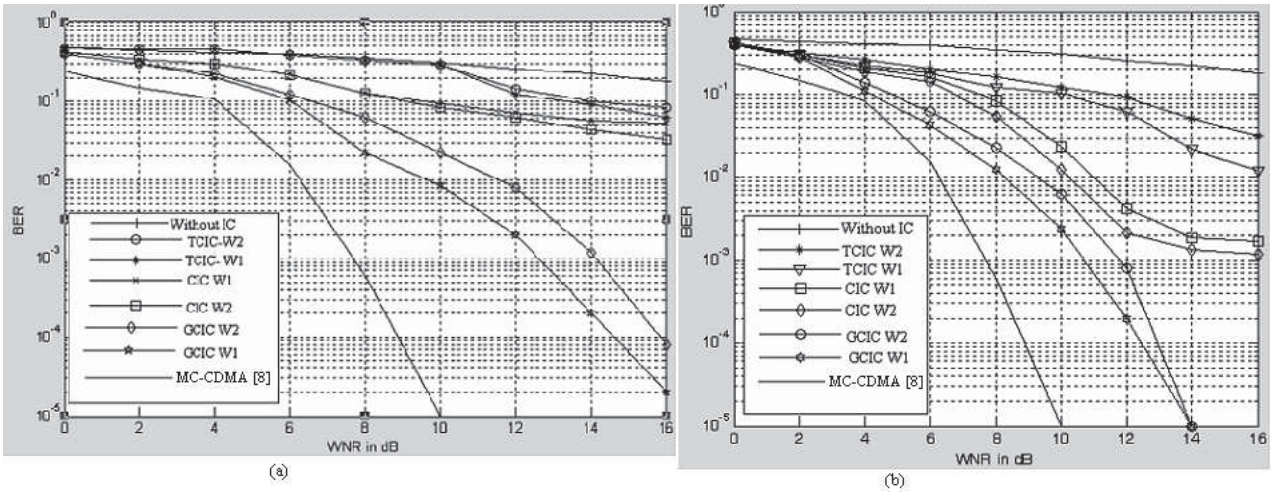

Fig. 7. BER performance through interference cancelation (a)with 1 iteration, (b) with 2 iterations

is available. Performance of the conventional CIC is better when the weights are calculated by W2, as detection of each watermark bit takes into consideration the subtraction (i.e cancelation) of interference due to every other embedded bits in one short. On the other hand, GCIC and TCIC show better performance when the weights are calculated assuming that the estimated data of the interfering bits is correct, as the strong watermark bits are detected first.

V. Conclusions and Scope of Future Work

Several versions of improved detection, namely CIC, TCIC and GCIC on MC-CDMA watermarking scheme are proposed and studied. Simulation results show that TCIC does not offer any BER performance improvement relative to CIC, while GCIC scheme offers significant improvement in BER performance and payload capacity. The proposed work may be extended for image error concealment. Extracted image digest (used as watermark) may be a representative measure of channel state information and feedback information may be sent to the receiver. This would help to design an adaptive system in terms of modulation, bit rate and power control in image transmission over fading channel.

On the Backhaul Reduction in Joint Transmission Network with Channel Uncertainty

Zhangxing Liu, Hui Tian, Cheng Qin
Beijing University of Posts and Telecommunications, Beijing 100876, China
Email: liuzhangxing000@sina.com

***Abstract*—Joint transmission (JT) has attracted broad attentions due to its ability to eliminate the intercell interference and to improve the system performance. JT needs to distribute the user data to the base stations (BSs) via backhaul before transmission hence it leads to consumption of backhaul links. In this paper, we consider a backhaul reduction scheme in multiple-input single-output (MISO) JT networks with incorporating the imperfect channel state information (CSI). Our goal is to design a robust procoder that minimizes the backhaul link consumption while satisfying the per-user quality of service (QoS) requirement. Due to the complexity of the original problem, we use the norm relaxation and semidefinite relaxation (SDR) to make the problem solvable. We further propose a link removal strategy based on the relaxed problem to minimize the backhaul consumption. Simulation shows that the proposed algorithm can reduce the backhaul consumption by at least 10.93% and 30.65% under different numbers of transmit antennas and users respectively.**

***Index Terms*—joint transmission, backhaul link consumption, channel uncertainty, norm relaxation.**

I. Introduction

With the increasing number of accessing equipment and data traffic volume, future networks will become more dense to provide the coverage and accommodation ability [1]. However, the dense cell deployment will incur severe inter-cell interference and deteriorate the system performance. Joint transmission (JT) is proposed to alleviate these interferences via cooperations among BSs. In JT, cooperative BSs can share the user data via backhaul links from the central processor (CP). These BSs can then transmit the desired signals to users simultaneously.

Although the JT can achieve a great improvement of system performance, the backhaul overhead becomes a main bottleneck. It is impractical for the full cooperation because of the finite capacity of backhaul. Data sharing scheme in JT is proposed in [2] in order to reduce the backhaul consumption. However, [2] only considers a information theoretical perspective. Therefore, different schemes for the reduction of the backhaul link consumption have been considered for practical systems [3]-[5]. In [3], the sum rate maximization is combined with the limited backhaul by designing beamforming. But it still concentrates on sum rate performance rather than backhaul reduction explicitly. In [4]-[5], the authors formulate the backhaul minimization problem into an ℓ_0 norm problem , which is inspired by compressive sensing. In [5], the authors uses an exponential function to approximate the ℓ_0 norm. [4] utilizes a ℓ_2 norm relaxation of the joint clustering and beamforming problem and then iteratively remove the links that correspond to the smallest link transmit power.

However, all the above literature discusses the problem with perfect CSI, which is obviously impractical. For the imperfect CSI, much literature has incorporated robustness to channel uncertainty into the formulation of the procoder design problem. [6] adopts the bounded CSI noise model and designs transceivers that optimize a worst-case QoS measure. It translates the problems into convex problems that can be solved efficiently as semidefinite programs (SDP). [7] assuming elliptically bounded CSI errors consider the worst-case robust design formulation that minimizes the weighted sum transmission powers of the BSs.

In this paper, we consider the transceiver design problem in the JT networks with limited backhaul. Our target is to minimize the backhaul consumption while providing a QoS guarantee for each user. The channel uncertainty is considered as well, which still lacks discussions in this problem to the best of our knowledge. The problem can be formulated into an ℓ_0 norm optimization, which is a non-convex and NP-hard problem. We first relax it into an ℓ_2 norm problem as [5]. Then we use the semidefinite relaxation method to transform the non-convex problem into a solvable convex SDP problem. Finally we propose a link removal method to force some beamforming vectors to zero and achieve lower backhaul consumption. The simulation results show that the proposed algorithm can significantly reduce the consumption of backhaul links, while satisfying the QoS requirement of each user.

The remainder of the paper can be organized as follows. In Section II, we provide the system model and the formulate a minimization problem of backhaul link consumption. We propose the method of link removal via semidefinite relaxation to solve the original problem in Section III. Simulation results are given in Section IV, and Section V concludes the paper. *Notation*: we use boldface letters to denote a matrix or vector. $(\bullet)^{\mathrm{T}}$ and $(\bullet)^{\mathrm{H}}$ stand for the transpose and conjugate transpose of a matrix respectively. $\mathrm{Tr}(\bullet)$ denotes the trace of a matrix. For any complex vector $\mathbf{x}$, we use $\|\mathbf{x}\|$ and $\|\mathbf{x}\|_0$ to represent the Euclidean norm and ℓ_0 norm respectivley. $\mathbf{A} \succeq \mathbf{0}$ denote the matrix $\mathbf{A}$ is semidefinite.

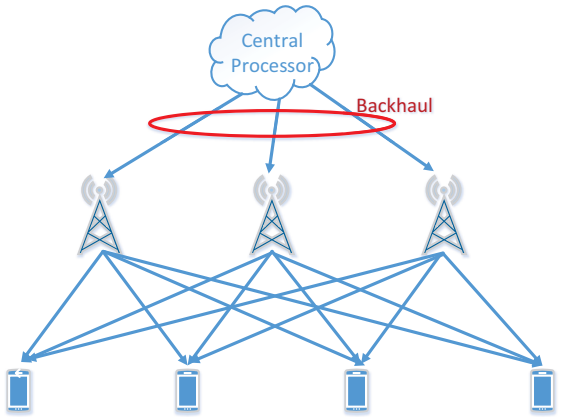

Fig. 1. Downlink joint transmission system model with the data sharing via backhaul from a CP.

II. System Model and Problem Formulation

Consider a downlink MISO joint transmission system consisted of M BSs and K single antenna users. We use $\mathcal{B}$ and $\mathcal{U}$ to denote the set of BSs and users respectively. Suppose that each BS is equipped with N_T transmit antennas. The BSs connect to a CP via limited backhaul links, as depicted in Fig. 1. Note we mainly focus on the limited capacity of the backhaul in this paper and the delay will not be considered. The CP will be responsible for the management of the network hence we can assume all user data and channel information are available at the CP.

Let $x_i \in \mathbb{C}$ be the desired signal for user i, which has a zero mean value and satisfies $\mathbb{E}\{|x|_i^2\} = 1$. Let $\mathbf{w}_{i,j} \in \mathbb{C}^{N\times 1}$ and $\mathbf{h}_{i,j} \in \mathbb{C}^{N\times 1}$ denote the transmit beamforming vector and the channel vector from BS j to user i. Here, we suppose the signal will experience a flat Rayleigh fading channel. Therefore, the received signal y_i at user i can be written as:

$$y_i = \sum_{j=1}^{M} \mathbf{h}_{i,j}^{\mathrm{H}} \mathbf{w}_{i,j} x_i + \sum_{k\neq i} \sum_{j=1}^{M} \mathbf{h}_{i,j}^{\mathrm{H}} \mathbf{w}_{k,j} x_k + n_i \qquad (1)$$

where n_i $\mathcal{CN}(0, \sigma^2)$ is the additive white Gaussian noise (AWGN) at user j.

At the receiver, each user will treat the inter-user interference as noise, thus the signal to noise plus interference ratio (SINR) of user i can be expressed as:

$$\mathrm{SINR}_i = \frac{|\sum_{j=1}^{M} \mathbf{h}_{i,j}^{\mathrm{H}} \mathbf{w}_{i,j}|^2}{\sum_{k\neq i} |\sum_{j=1}^{M} \mathbf{h}_{i,j}^{\mathrm{H}} \mathbf{w}_{k,j}|^2 + \sigma^2} \qquad (2)$$

In general cases, JT requires a full cooperation among all BSs, i.e., all BSs will transmit useful signals to the users. This feature will incur large backhaul overhead. In [4][5], the partial cooperation in JT is proposed hence some BSs can be treated as muted from the perspectives of users. Particularly, when $\mathbf{w}_{i,j} = 0$, it means that the data for user i will not be shared at BS j via the backhaul link. In this way, the backhaul overhead can be reduced since some data will not be transmitted on the backhaul. Similar to [4], we use the number of non-zero $\mathbf{w}_{i,j}$ to model the backhaul consumption. Therefore, the ℓ_0 norm is introduced and the sum backhaul link consumption for user i can be modeled as:

$$C_i = \| |\mathbf{w}_{i,1}|, |\mathbf{w}_{i,2}|, \cdots, |\mathbf{w}_{i,M}| \|_0 \qquad (3)$$

On the other hand, we assume an imperfect CSI in this paper and consider additive uncertainty channel models for the system. Therefore, the channel can be given as:

$$\mathbf{h}_{i,j} = \tilde{\mathbf{h}}_{i,j} + \mathbf{e}_{i,j}, \quad \forall i \in \mathcal{U}, \forall j \in \mathcal{B} \qquad (4)$$

where $\tilde{\mathbf{h}}_{i,j}$ is the estimated channel which is available at the BS. $\mathbf{e}_{i,j}$ is the channel estimation error which is assumed to be bounded as $\|\mathbf{e}_{i,j}\| \leq \delta_{i,j}$ for a given $\delta_{i,j}$.

Our target is to minimize the backhaul consumption of the system. Meanwhile, the QoS should be guaranteed for each specific user hence we give a SINR threshold γ_i for each user. Therefore, we formulate the backhaul link consumption minimization problem with SINR constraints as follows:

$$\begin{aligned} \min_{\{\mathbf{w}_{i,j}\}} \quad & \sum_{i=1}^{K} C_i \\ \text{subject to} \quad & \mathrm{SINR}_i \geq \gamma_i \\ & \|\mathbf{e}_{i,j}\| \leq \delta_{i,j} \\ & \forall i \in \mathcal{U}, \quad \forall j \in \mathcal{B} \end{aligned} \qquad (5)$$

The above problem is non-trivial due to two reasons. First, the QoS constraints in (5) makes the problem non-convex because the variables are coupled in the fractional expressions. Additionally, the objective function of (5) is a non-smooth function. Although exhaustive method or branch-and-bound (BB) algorithm can be used for addressing this difficulty, the complexity of these methods is too high hence they are prohibitive in practice. To handle these difficulties, in the next section, we will reformulate the non-convex constraints into a cone form and then propose a norm relaxation strategy for the non-smooth objective function.

III. Link Removal via Semidefinite Relaxation

In this section, we first propose to relax the ℓ_0 norm function into a solvable and convex function. Observe the QoS constraints, we reformulate these expressions into cone forms and use the convex toolbox to solve it. After achieving a group of solutions, we use a link removal strategy to minimize the consumption of backhaul links.

A. Problem reformulation based on relaxations

According to the definition of ℓ_0 norm, the following equation always holds:

$$\| [|\mathbf{w}_{i,1}|, \cdots, |\mathbf{w}_{i,K}|] \|_0 \triangleq \left\| \left[|\mathbf{w}_{i,1}|^2, \cdots, |\mathbf{w}_{i,K}|^2 \right] \right\|_0 \qquad (6)$$

Therefore, the sum backhaul link consumption for user i can be rewritten as given in (7):

$$C_i = \left\| \left[\mathbf{w}_{i,1}^H \mathbf{w}_{i,1}, \mathbf{w}_{i,2}^H \mathbf{w}_{i,2}, \cdots, \mathbf{w}_{i,K}^H \mathbf{w}_{i,K} \right] \right\|_0 \qquad (7)$$

For a vector, the ℓ_0 norm returns the number of non-zero elements of the vector.

Due to the non-smooth feature appears in (7), a simple approximation of ℓ_0 norm is to substitute this function by ℓ_2 norm, which is first introduced in compressive sensing [3][5]. Applying the idea of replacing the ℓ_0 norm by the ℓ_2 norm, we can first relax (5) to the following optimization problem:

$$\begin{aligned} \min_{\{\mathbf{w}_{i,j}\}} \quad & \sum_{i,j} \mathbf{w}_{i,j}^H \mathbf{w}_{i,j} \\ \text{subject to} \quad & \text{SINR}_i \geq \gamma_i \\ & \|\mathbf{e}_{i,j}\| \leq \delta_{i,j} \\ & \forall i \in \mathcal{U}, \quad \forall j \in \mathcal{B} \end{aligned} \tag{8}$$

Note the SINR constraints are still non-convex in (8). We first define $\mathbf{w}_i = \left[\mathbf{w}_{i,1}^H, \mathbf{w}_{i,2}^H, \cdots, \mathbf{w}_{i,M}^H\right]^H \in \mathbb{C}^{MN\times 1}$, which represents the downlink transmit beamforming vector from all BSs to user i, and in the same way we define $\mathbf{h}_i = \left[\mathbf{h}_{i,1}^H, \mathbf{h}_{i,2}^H, \cdots, \mathbf{h}_{i,M}^H\right]^H \in \mathbb{C}^{MK\times 1}$ and $\mathbf{e}_i = \left[\mathbf{e}_{i,1}^H, \mathbf{e}_{i,2}^H, \cdots, e_{i,M}^H\right]^H \in \mathbb{C}^{MK\times 1}$. Using the definition above, the problem (8) can be reexpressed, as given in (9):

$$\begin{aligned} \min_{\{\mathbf{w}_i\}} \quad & \sum_i \mathbf{w}_i^H \mathbf{w}_i \\ \text{subject to} \quad & \left(\tilde{\mathbf{h}}_i^H + \mathbf{e}_i^H\right) \mathbf{A} \left(\tilde{\mathbf{h}}_i + \mathbf{e}_i\right) - \sigma^2 \geqslant 0, \\ & \|\mathbf{e}_i\|^2 \leqslant \sum_{j=1}^{M} \delta_{i,j}^2, \\ & \forall i \in \mathcal{U}, \quad \forall j \in \mathcal{B} \end{aligned} \tag{9}$$

where $\mathbf{A} = \frac{1}{\gamma_i}\mathbf{w}_i\mathbf{w}_i^H - \sum_{k\neq i}^{K} \mathbf{w}_k\mathbf{w}_k^H$.

To eliminate the quadratic form of $\mathbf{w}_{i,j}$, we can use the semidefinite relaxation (SDP) method to make (9) solvable. We further let $\mathbf{W}_i = \mathbf{w}_i\mathbf{w}_i^H$ to substitute $\mathbf{w}_{i,j}$. To keep an equivalence of the transformation, we add constraints to force the rank of $\mathbf{W}_i$ to 1. Therefore, we can reformulate the problem (9) as follows:

$$\begin{aligned} \min_{\{\mathbf{W}_i\}} \quad & \sum_i \text{Tr}(\mathbf{W}_i) \\ \text{subject to} \quad & \left(\tilde{\mathbf{h}}_i^H + \mathbf{e}_i^H\right) \mathbf{X}_i \left(\tilde{\mathbf{h}}_i + \mathbf{e}_i\right) - \sigma^2 \geqslant 0, \\ & \|\mathbf{e}_i\|^2 \leqslant \sum_{j=1}^{M} \delta_{i,j}^2, \\ & \mathbf{W}_i \succeq \mathbf{0}, \text{rank}(\mathbf{W}_i) = 1 \\ & \forall i \in \mathcal{U} \end{aligned} \tag{10}$$

where $\mathbf{X}_i = \frac{1}{\gamma_i}\mathbf{W}_i - \sum_{k\neq i}^{K} \mathbf{W}_k$.

Because of the rank one constraint, the problem (10) is still non-convex. However, in SDR, we can relax the above problem by dropping the rank one constraint. If the relaxation is tight, we can always recover $\mathbf{w}_i$ from $\mathbf{W}_i$. Therefore, after the relaxation (10) becomes convex and can be easily solved by applying the following S-procedure.

Lemma 1: ([8], S-procedure) Let $f_i(\mathbf{x}) \triangleq \mathbf{x}^H\mathbf{A}_i\mathbf{x} + \mathbf{b}_i^H\mathbf{x} + \mathbf{x}^H\mathbf{b}_i + c_i$, for $i = 0, 1$,where $\mathbf{A}_i$ is a Hermitian matrix.

Algorithm 1 Link removal via semidefinite relaxation

Require: Minimizing the consumption of backhaul links
  Solve the problem (8) using semidefinite relaxation
  if not convergent **then**
    The problem (8) is infeasible. Exit to link adaptation
  else
    Sort the data streams according to $\|\mathbf{w}_{ij}\|^2$.
    Initialize $Q_{\min} = 0$, $Q_{\max} = (M-1)K$, $Q = \lfloor (Q_{\min} + Q_{\max})/2 \rfloor$.
    while $Q_{\max} - Q_{\min} \geqslant 2$ **do**
      Solve the problem (12) using demidefinite relaxation
      if not convergent **then**
        $Q_{\max} = Q, Q = \lfloor (Q_{\max} + Q_{\min})/2 \rfloor$;
      else
        $Q_{\min} = Q, Q = \lfloor (Q_{\max} + Q_{\min})/2 \rfloor$;
      end if
      Sort the data streams according to $\|\mathbf{w}_{ij}\|^2$.
    end while
    Return Q and its corresponding $\{\mathbf{w}_{i,j}\}$.
  end if

Suppose that there exists an $\bar{\mathbf{x}}$ and $f_1(\bar{\mathbf{x}}) \leqslant 0$. Then the two conditions are equivalent:

1) $f_0(\mathbf{x}) \geqslant 0$ for all $\mathbf{x}$ satisfying $f_1(\mathbf{x}) \leqslant 0$;
2) There exists a $\lambda \geqslant 0$ such that

$$\begin{bmatrix} \mathbf{A}_0 & \mathbf{b}_0 \\ \mathbf{b}_0^H & c_0 \end{bmatrix} + \lambda \begin{bmatrix} \mathbf{A}_1 & \mathbf{b}_1 \\ \mathbf{b}_1^H & c_1 \end{bmatrix} \succeq \mathbf{0}.$$

By applying *Lemma 1* to (10), we can transform (10) to the following problem:

$$\begin{aligned} \min_{\{\mathbf{W}_i\}} \quad & \sum_i \text{Tr}(\mathbf{W}_i) \\ \text{subject to} \quad & \begin{bmatrix} \mathbf{X}_i + \lambda_i\mathbf{I} & \mathbf{X}_i\tilde{\mathbf{h}}_i \\ \tilde{\mathbf{h}}_i^H\mathbf{X}_i^H & \tilde{\mathbf{h}}_i^H\mathbf{X}_i\tilde{\mathbf{h}}_i - \sigma^2 - \lambda_i \sum_{j=1}^{M} \delta_{ij}^2 \end{bmatrix} \succeq \mathbf{0}, \\ & \mathbf{W}_i \succeq \mathbf{0}, \forall i \in \mathcal{U} \end{aligned} \tag{11}$$

Now the SINR constraints are transformed to cone forms, which is convex. Hence (11) is a standard convex SDP, which can be efficiently solved via convex toolbox [9].

The optimal solution $\{\mathbf{W}_i\}$ is obtained from the rank relaxation, however, this relaxation cannot guarantee to be tight. Here we discuss two different situations: If each of the optimal solution $\{\mathbf{W}_i\}$ happens to be of rank one, which suggests a tight relaxation, we can get the optimal solution $\{\mathbf{w}_{i,j}\}$ for (8) from $\mathbf{W}_i = \mathbf{w}_i\mathbf{w}_i^H$ for all i, j. On the other hand, if the rank of $\{\mathbf{W}_i\}$ is larger than one, we can consider the idea of applying a rank-one approximation on $\{\mathbf{W}_i\}$, see [10] for the details. By using *Proposition 1* in [7], we know that the optimal solution of SDR in this paper can always guarantee to be rank one, which means that the relaxation is tight and the optimal solution $\{\mathbf{w}_{i,j}\}$ for (8) can always be obtained.

B. Link removal

The optimal solution $\{\mathbf{w}_{i,j}\}$ obtained by SDR cannot guarantee the minimum backhaul link consumption. It is because the solutions are not forced to be sparse. Therefore, we further propose to achieve sparse beamforming vectors. Note that decreasing the backhaul consumption means more $\{\mathbf{w}_{i,j}\}$ to be zero, so we can use a link removal strategy similar to [6] to deal with those non-zero solutions of $\{\mathbf{w}_{i,j}\}$.

Firstly the data streams can be sorted according to the $\|\mathbf{w}_{i,j}\|^2$, which means the transmission power allocated from BS j to user i, from the lowest to the highest, and $Num_{i,j}$ represents the sequence number. Then we can set the lowest non-zero $\{\mathbf{w}_{i,j}\}$ to be zero. It is because when $\mathbf{w}_{i,j}$ is small, the BS i will only allocate few power for user j. Similar to the idea of water-filling, it brings little improvement if BS i transmits signal to user j. Therefore, this link can be removed in order to save the backhaul resources. After the removal of the lowest $\mathbf{w}_{i,j}$, we can solve a new problem, which can be given as follows:

$$\begin{aligned} \min_{\{\mathbf{w}_{i,j}\}} \quad & \sum_{i,j} \mathbf{w}_{i,j}^H \mathbf{w}_{i,j} \\ \text{subject to} \quad & \text{SINR}_i \geq \gamma_i \\ & \|\mathbf{e}_{i,j}\| \leq \delta_{i,j} \\ & \mathbf{w}_{ij} = \mathbf{0}, \text{when } Num_{i,j} \leqslant Q \text{ and} \sum\nolimits_j \mathbf{w}_{i,j} \neq \mathbf{0} \\ & \forall i \in \mathcal{U}, \quad \forall j \in \mathcal{B} \end{aligned} \tag{12}$$

where Q represents the number of links removed from data transmission.

In the process, we must keep at least one $\mathbf{w}_{ij} \neq 0$ for each user i, which implies that keeping the link from its serving BS for data transmission. We can increase Q from 1 to $(M-1)K$ to search the optimal solution, which also leads to much complex computations. And to avoid it, we adopt the bisection method to accelerate the link removal scheme. The link removal via semidefinite relaxation method is summarized in the Algorithm 1.

IV. Simulation

In this section, we evaluate our proposed algorithm under different system configurations. We consider a network of $M = 3$. The downlink channel between the BS and each user is generated according to identically complex Gaussian distributions. Assume that the channel estimation errors δ_{ij} and the QoS requirements γ_i for different users are identical, i.e., $\delta_{ij} = \delta, \gamma_i = \gamma, \forall i \in \mathcal{U},\ j \in \mathcal{B}$. All the simulations are averaged over 100 random channel realizations. The scheme of full cooperation among all BSs in the network is used as a benchmark in the evaluations.

First we test the proposed algorithm under a fixed user number of $K = 6$. Fig.2 shows the performance of backhaul link consumption versus the various number of antennas. We also present the percentages of backhaul link reduction which are compared to the full cooperation scheme in Fig. 3. Different channel estimation errors and QoS requirements are considered as well. As we can see in these two pictures, the backhaul consumption can be remarkably reduced by using the proposed algorithm. The curves of perfect CSI provide a lower bound of the consumption. When the error of channel estimation increases, the performance will decrease because of the inaccurate channel information. From Fig. 3, it also reveals that stringent QoS will leads to more backhaul overhead because more BSs will be used for JT in order to achieve a higher SINR. On the other hand, we can see that the backhaul consumption will decrease with increasing number of transmit antennas. It demonstrates that the proposed algorithm can achieve a better performance when the BSs are equipped with large number of antennas. It should be noted that when N_T reaches a large number, e.g., $N_T = 6$ in Fig. 2, different channel error estimation or QoS will no longer affect the performance. It is because the serving BS of each user can almost satisfy the requirement alone and JT will not be used

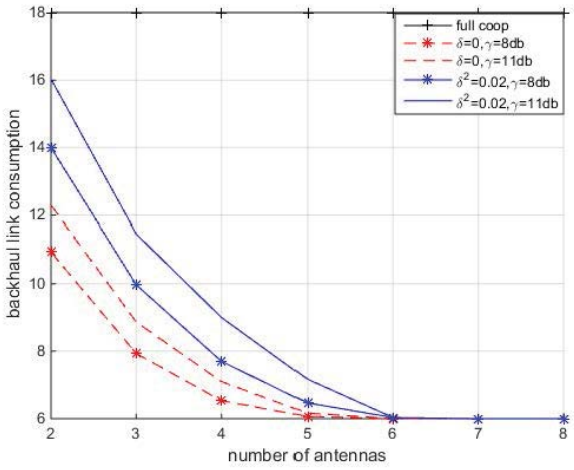

Fig. 2. Backhaul link consumption versus different number of antennas.

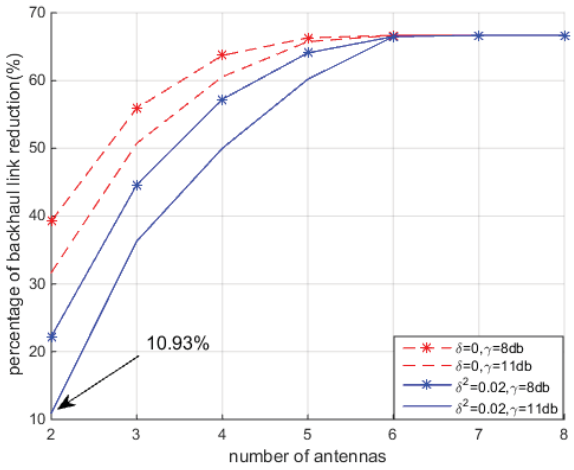

Fig. 3. Percentage of backhaul link reduction compared to full cooperation.

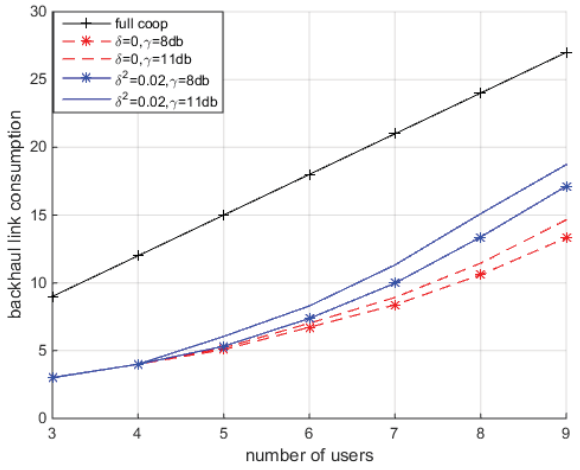

Fig. 4. Backhaul links consumption versus different number of users.

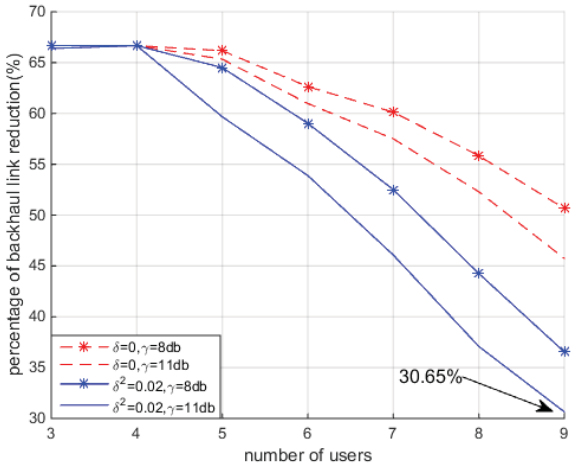

Fig. 5. Percentage of backhaul link reduction compared to full cooperation.

at this moment. Hence the backhaul consumption will reach a minimum value. As we can see from Fig. 3, the backhaul reduction will be more remarkable with an uncertain channel information or high QoS when the number of transmit antenna increases. This is because when N_T is small, the proposed algorithm will result in limited performance under imperfect CSI or stringent QoS. However, when N_T becomes larger, our strategy will become more effective and lead to a better improvement. Under the worst case (when $N = 2$, $\gamma = 11$db and $\delta^2 = 0.02$), the proposed algorithm can at least reduce the consumption of backhaul links by 10.93%.

Fig.4 shows the performance of backhaul link consumption versus the various number of users. In this figure, we set the number of transmit antennas at each BS as $N_T = 4$. We can also see that a worse channel estimation or higher QoS will lead to a performance deterioration. Fig. 4 illustrates that the channel uncertainty or QoS requirement will not affect the proposed algorithm when K is small. The reason is that the inter-user interference is much lower in this case, therefore the proposed algorithm can still keep the backhaul consumption on a substantial lower level. However, with the increasing number of users, the number of backhaul links for JT will also increase in order to satisfy the transmission requirement, as shown in Fig. 4. From Fig. 5, we can see that the percentage of backhaul link reduction compared will reduce when K is large. Particularly, this performance will drop more obvious when the channel is imperfect or the QoS is high. But the proposed algorithm can still achieve an acceptable performance improvement compared to the full cooperation. As shown in Fig. 5, when $K = 9$, $\gamma = 11$ db and $\delta^2 = 0.02$, the proposed algorithm can still substantially reduce the consumption of the backhaul links by 30.65%.

V. Conclusion

In this paper, we consider a backhaul reduction algorithm in JT systems with channel uncertainty and QoS requirement. We formulate the scheme as a non-convex and non-smooth optimization. Due to the difficulties in addressing the original problem, we use the norm relaxation and transform it to a convex SDP via SDR method. We further propose an link removal strategy based on the relaxed problem to minimize the backhaul link consumption. The imperfect CSI is incorporated therefore our algorithm can be applied in practical systems. From the simulation it can be found that the proposed algorithm can reduce the backhaul consumption remarkably while satisfying the transmission requirement comparing with the traditional full cooperation scheme.

Abstract— **This paper proposes an intelligent resource management scheme for multi-hop data collection that is effective for big-data management system deploying Smart Utility Network (SUN) – Regional Area Network (RAN) integrated topology where each RAN radio device plays a role of SUN Collection Station (CS) and collects data from several SUN devices in its assuming SUN area and further forward the collected data towards the RAN CS. In the proposed system, the dedicated system resources for each SUN and RAN system are flexibly and effectively allocated for date forwarding according to each topology that is seriously affected by data traffic. In order to realize such resource management, a dynamic resource management technology for each forwarding device in RAN and superframe division data aggregation technology in SUN are proposed respectively. Especially in this paper, the latter technology in SUN is investigated from the viewpoint of forwarded data traffic to RAN devices. Computer simulation results confirm that the proposed superframe division data aggregation technology achieves about 10 times improvement on the forwarded data traffic for RAN.**

Keywords—SUN; RAN; IEEE 802.15.4e; aggregation; multi-hop

I. INTRODUCTION

SUN for effective data collection from a large number of gas, water, and/or electric meters, to provide data to data-collection stations [1] would be a typical radio-based system in the smart grid structure. SUNs can reduce the labor cost in meter-reading by using radio transmission and are expected to provide comprehensive data collection free of oversight. They also appear highly effective in terms of providing safety and, moreover, they are noted for their potential to support two-way communications that can be utilized to measure intelligent energy consumption management in residences and neighborhoods. SUNs' collective benefits make them one of the most likely components in the smart grid structure. Since SUNs are seen as such promising systems, a worldwide movement for their standardization is underway. One of the most aggressive standardization organizations is the IEEE 802 committee, in which the IEEE 802.15.4g task group [2] standardized the PHY amendment for the IEEE 802.15.4 standard [3] to support SUNs. Meanwhile, the IEEE 802.15.4e task group [4] standardized the MAC modification required to realize an effective PHY amendment. Since both forms of standardization were finalized in March 2012, the world first certification body of conformance and interoperability tests on those standard-based radio devices was established – the Wireless-SUN (Wi-SUN) alliance [5] – which actively promotes popularization of SUN devices by defining Wi-SUN profile specifications based on several assumed applications. Since the Wi-SUN alliance has started its activities of certifying IEEE 802.15.4g based SUN devices according to the several expected profiles, further diversified applications employing SUN are considered. ECHONET Lite [6], the communication protocol standard for a home energy management system (HEMS), is one such application supported by the dedicated Wi-SUN profile. This profile for ECHONET Lite is already included in the Japanese standard of radio specifications for ECHONET Lite and the Japanese major ten electric power corporations including Tokyo Electric Power Corporation (TEPCO) are going to deploy it in 80 million houses. Besides ECHONET Lite, deployment of the Wi-SUN profile is also expected in further expanded applications such as the wireless sensor networks, machine-to-machine (M2M) networks or Internet of Things (IoT) with a variety of traffic in the future.

Since the assumed SUN system has a short radio range up to about 1km, another comprehensive communication measure is required in order to provide a data collection from a large area such as regional area. RAN that is also standardized in IEEE 802 as the IEEE 802.22b [7] is expected as one of good candidate because it can provide relatively longer radio link than SUN, that is more than 10km. The RAN-SUN integrated system where data in a SUN area is once collected on a RAN device and then forwarded among the RAN devices towards the RAN CS is one of the most typical systems considering the feasible data collection.

How to cope with the large amount of data is one of the most important issues for general data collection systems as well as the RAN-SUN integrated system. The issue becomes further serious for the case of big-data management using radio communication because effective data collision avoidance

technologies need to be realized by utilizing the allocated frequency resources to the system.

Therefore, in this paper we propose an intelligent resource management scheme for the RAN-SUN integrated data collection system where the dedicated system resources for each SUN and RAN system are flexibly and effectively allocated for date forwarding according to each topology that is seriously affected by data traffic. In order to realize such resource management, a dynamic resource management technology for each forwarding device in RAN and superframe division data aggregation technology in SUN are proposed respectively. Especially in this paper, the latter technology in SUN is investigated from the viewpoint of forwarded data traffic to RAN devices.

The rest of this paper is organized as follows. The next section presents an overview of the assumed system image of RAN-SUN integrated system. In section III, the concept of resource management for the RAN-SUN integrated system for data collection. Section IV explains the proposed superframe division multi-hop data collection with frame aggregation in SUN system. Section V presents computer simulation evaluation of the proposed scheme. The final section concludes the paper.

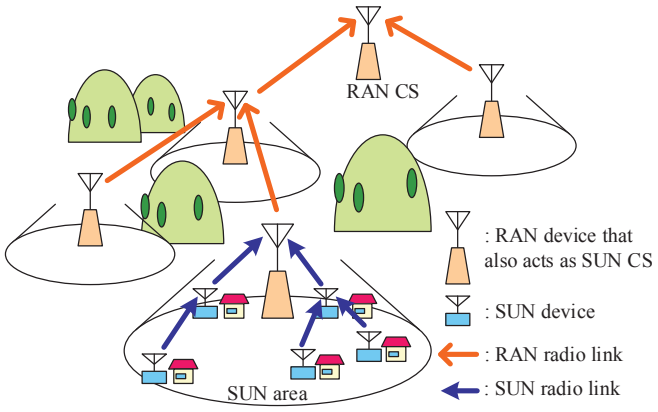

Figure 1. Assumed RAN-SUN integrated system

II. Overview of Assumed RAN-SUN Integrated System for Data Collections

Fig. 1 is a schematic of the assumed RAN-SUN integrated system for data collection. Each of more than one SUN based data collection systems is connected to the one RAN device that has a function of SUN CS. Such collected data in each SUN area is also forwarded among the RAN devices towards the RAN CS that becomes a total data collection station in the RAN-SUN integrated system.

In the SUN system that is standardized as IEEE 802.15.4g/4e, low-energy operation capability and multi-hop transmission capability are regarded as the two most important features. The former means that radio device operations under battery-driven conditions or restricted power supply conditions are required. The latter means the requirements of guaranteeing the assumed service area regardless of radio link degradations owing to pass loss or shadowing loss.

On the other hand, in the RAN system that is standardized as IEEE 802.22b, broadband radio transmission capability accompanied with the multi-hop transmission capability is considered as the key features of the system, which is also expected to work effectively for the assumed data collection system in the regional area as depicted in Fig. 1.

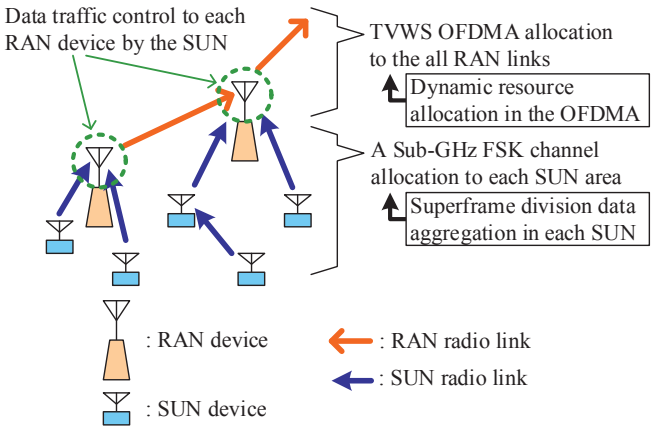

Figure 2. Concept of the resource management for the assumed RAN-SUN integrated system

III. Concept of the Resource Management for the RAN-SUN Integrated System

Fig. 2 shows the concept of the resource management for the assumed RAN-SUN integrated system. The most remarkable point here is that there are different specifications between those two systems each of them are independently standardized by employing different frequency band, modulation scheme and so on, but the two systems are also dependent on each other since they have the deal on the collected data forwarding. Therefore, there would be the possible constructive approaches from both systems to improve the total system performance.

In the SUN system, allocated frequency band for the system is different among the assumed deployed region [2], out of which 920 MHz band for Japan region or 910 MHz band for US region would be the typical allocations in the standard. Frequency Shift Keying (FSK) is most famous Physical (PHY) layer mode in the standard as the Wi-SUN alliance promotes. As for the low-energy multi-hop transmission as strongly required in the system, several research are conducted as in [8]-[13]. Among them, a control scheme that employs superframe division data aggregation technology [14] that is compliant to the IEEE 802.15.4e is considered to be effectively applied to the assumed RAN-SUN integrated system in the viewpoint of not only data flow control in the SUN but also forwarded data traffic control to the RAN. The details of the superframe division data aggregation technology is explained in the next section.

In the RAN system, allocation of TeleVision White Space (TVWS) band with employment of Orthogonal Frequency Division Multiple Access (OFDMA) are considered. Thus, dynamic subcarrier allocation according to the forwarded data traffic for each RAN device is considered as one of the most effective technologies to improve the total system performance

by harmonizing with the management in the SUN system. Since this paper is mainly focusing on the resource management in the SUN as described in the next section, the details of resource management for the RAN system and evaluation of that would become the future study.

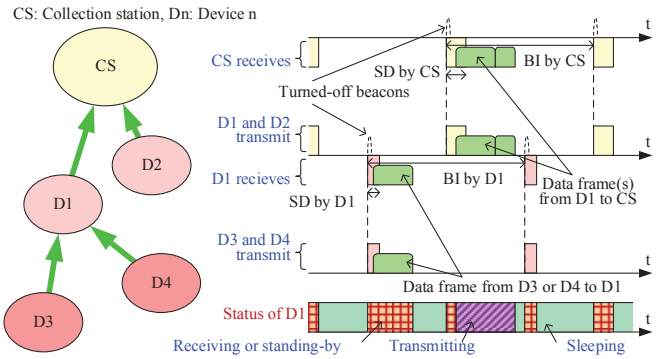

Figure 4. Example of data frame relaying to SUN CS

IV. SUPERFRAME DIVISION MULTI-HOP DATA COLLECTION WITH FRAME AGGREGATION FOR SUN

Fig. 3 shows the superframe structure as defined in IEEE802.15.4e MAC, namely a low-energy (LE) superframe [4]. As standardized in [4], Full Function Devices (FFDs) can act as coordinators in the topology and manage time slot allocation by broadcasting beacons, thus they can be referred to as superframe coordinators in this paper. A beacon interval (BI) is divided into an active and inactive period, as depicted in the figure, and associating devices can enter the sleep state during the inactive period. An active period, also denoted as superframe duration (SD) in its length, assumes a contention access period (CAP) without a contention-free period (CFP). Slotted CSMA-based contention access is adopted during the CAP. BI and SD are defined as BI = 960 *2^BO (symbols) and SD = 960*2^SO, respectively, by using parameters of BO and SO. Here, 0<=SO<=BO<=14. Especially in the LE superframe case, periodical broadcasting of the beacon can be omitted to reduce power consumption from wasted transmission by providing two options for such beacon broadcasting. The first option is where there is no beacon broadcasting except for when the beacon is clearly requested to transmit; i.e., on-demand beacon broadcasting. The other is periodical but intermittent beacon broadcasting. For this, a period of a practical beacon interval equivalent to a multiple of BI is determined and held as a parameter. In this paper, an on-demand beacon is employed in the following computer simulations and experiments. A relatively short active period without a CFP is selected to reduce unintended reception during the active period. For a shortened active period, frame transmission that starts during the period may end before the beacon period not in the current active period, as shown in Fig. 3. Devices receiving a transmitted frame continue reception until complete, even if the active period has ended. Because of this modification, devices not addressed by the frame or not interested in the frame can enter the sleeping state just after such a period, wherein not only the receiver but also all other devices should be standing by, and this helps reduce power consumption. In this paper we also assume frame aggregation [14], as in Fig. 3. The figure also depicts that the frame aggregation in the LE superframe is not restricted by an active period length and can effectively carry the aggregated frame.

Fig. 4 shows the performance of data frame relaying in the current topology. Here, the CS accommodates two meter nodes (D1 and D2), and the other two (D3 and D4) are associating meters with D1. For example, D3 and D4 operate according to the superframe defined by D1 when they send each frame to it. D1 obeys the superframe defined by its associating the CS when D1 relays the received frames to the CS. A meter such as D1 must change its own state according to both incoming and outgoing superframes, as defined in IEEE 802.15.4 MAC. Moreover, we should note that frames in the different superframes (such as those from D2 and D3) expect a very low probability of collision with LE superframe deployment. Thus, we will increase the number of superframes independently by different superframe coordinators in order to instead decrease the frame collisions.

Fig. 5 shows the concept of superframe division multi-hop data collection with frame aggregation in the tree topology constructed by a CS and meter nodes. Here, radio links grouped by the sharing superframe and expected frames on them are shown, assuming each SUN device generates one data frame addressed to the CS. Fig. 5(a) shows the basic case without superframe division or aggregation techniques. Here, a large number of frames, including relayed ones, are provided to the CS and data collection throughput degradation owing to the bottleneck problem can easily be expected. Fig. 5(b) shows the same situation except for frame aggregation. In this case, some frames, including relayed ones, are aggregated into one frame by the relaying devices, thereby decreasing the number of frames reaching the CS. However, frames on the radio links sharing the same superframe can cause collisions, as in Fig. 5(b). In the Fig. 5(c) case with superframe division with aggregation, additionally defined superframes reduce the number of links in the shared superframe, which is expected to reduce frame collision per superframe and mitigate the bottleneck. The additional superframe can be realized by restricting the number of links in a superframe that is equivalent to that for associating devices to a superframe coordinator. Though the average number of hops to the CS is also increased with such superframe division, bottleneck mitigation capability is expected to improve total throughput performance.

V. COMPUTER SIMULATION RESULTS

Evaluations via computer simulation were conducted to investigate the performance of the proposed scheme. Table 1 lists the simulation conditions. A square-shaped simulation area is considered in which one collection station is located at the center and 1,000 meters are uniformly scattered. Transmission power of 20 mW in the 920-MHz frequency band is set in accordance with the IEEE 802.15.4g specifications defined for use in Japan that are also included in the Wi-SUN profile for ECHONET Lite. Such PHY parameters are proposed as the dominant transmission rate in IEEE 802.15.4g. A fixed beacon interval of 9.83 s by a BO value of 10 is assumed, which is determined according to the application type and required delay performance. The active period length is examined at 76.8 ms, employing SO values of 3, which means the active period ratio of 0.8%. In the simulation we employ payload lengths of 100 octets by assuming short data collection in SUN. In the simulation, frames periodically arrive on each meter node and all frames are addressed to the CS. In the simulations, we have two major parameters: maximum aggregation size S_{agg} and maximum radio links or devices sharing a superframe N_{DEV}.

TABLE I. SIMULATION CONDITIONS

Parameter	*Value*
Simulated SUN area	2 km x 2 km square area where CS located centered
Number of SUN devices	1,000 devices in a SUN
Frequency band	920 MHz
Transmission power	20 mW
Path loss model	ITU-R P.1411-6 [15]
Shadowing model	Log-normal with standard deviation of 4.0 dB
Receiver sensitivity	-88 dBm
Modulation scheme	100 kbps, 2 GFSK
Beacon interval	9.83 s (BO = 10)
Active period lengths	76.8 ms (SO = 3)
Frame payload length	100 octets (8 ms)
Routing scheme	Tree routing
Frame arrival	Periodical per each meter node
Frame timeout	Same as arrival interval

Fig. 6 shows the frame success probability for the superframe division data aggregation technology according to data frame interval. Several S_{agg} values are investigated in the figure where S_{agg} = 1 means the case that no aggregation is conducted. Fig. 6 shows the frame success probability is improved according to the employed aggregation size, while saturated in about S_{agg} = 16 case. The value of the other parameter N_{DEV} is set to the most effective value as shown in the following Fig. 7.

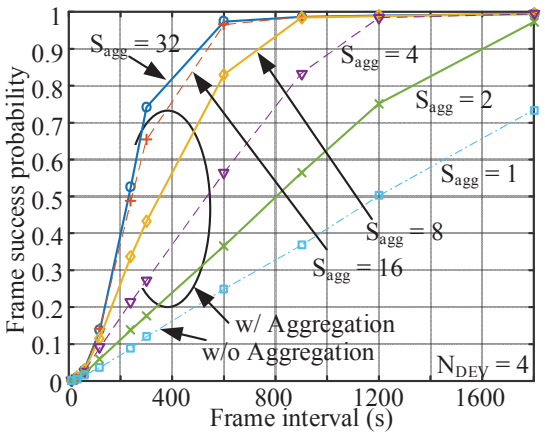

Figure 6. Frame success probability for the superframe division data aggregation according to data frame interval

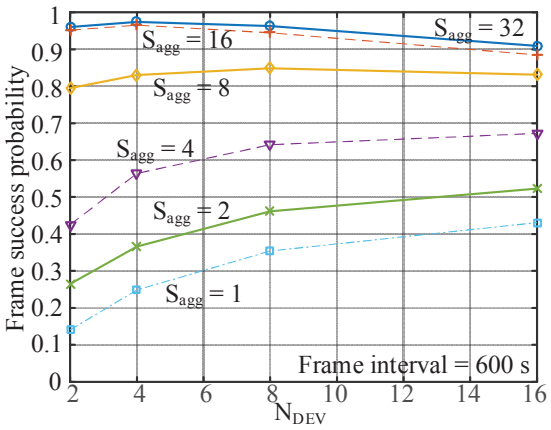

Figure 7. Frame success probability for the superframe division data aggregation according to N_{DEV}

Fig. 7 shows the performance according to N_{DEV} in the case with a 10-min. frame interval. The figure shows that the best performances are provided in the case with larger aggregation size when N_{DEV} is set to about 4. Such situation means the employed superframe division data aggregation is most effectively carried out. It confirms that performance can be improved by more than 95% with the largest aggregation size.

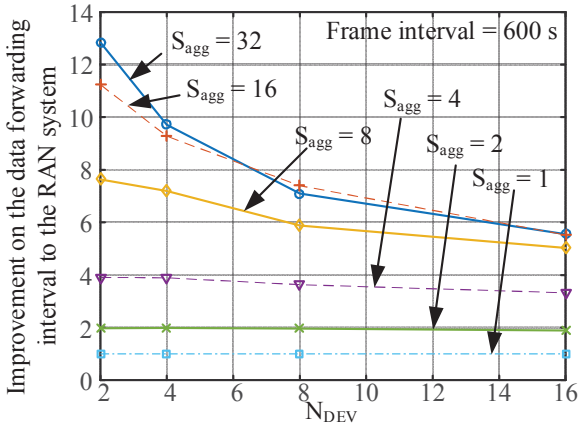

Figure 8. Improvement on the data forwarding interval to the RAN system according to N_{DEV}

Finally, improvement on the data forwarding interval to the RAN system is shown in Fig. 8. Here, the improvement is defined as the normalized forwarding interval for the aggregated data frames by that for the case no aggregation is employed. Fig. 8 shows that about 10 times improvement is possible with the suitable conditions, which results are expected to work effectively for the total system performance of the assumed SUN-RAN integrated data collection system.

VI. CONCLUSIONS

This paper proposes an intelligent resource management scheme for multi-hop data collection that is effective for big-data management system deploying SUN-RAN integrated topology In order to realize an effective resource management for each SUN and RAN system, a dynamic resource management technology for each forwarding device in RAN and superframe division data aggregation technology in SUN are proposed respectively. Furthermore, superframe division data aggregation technology for the SUN is investigated from the viewpoint of forwarded data traffic to RAN devices. Computer simulation results confirm that the proposed superframe division data aggregation technology achieves about 10 times improvement on the forwarded data traffic for RAN. Detailed resource management for RAN system and the total evaluation on the entire SUN-RAN integrated system is a topic for our future studies.

Hyderabad, INDIA.

***Abstract*—In this paper, we consider simultaneous transmission of information and energy in a wireless network with channels undergoing frequency-selective fading. The receivers can decode the information as well as harvest energy from the same received signal. The network employs orthogonal frequency division multiplexing (OFDM) for signal transmission. We consider two different problems in the simultaneous transmission of information and energy and propose algorithms for transmit and receive processing. The first problem is the optimal resource allocation for maximizing weighted sum-rate of the users while guaranteeing a minimum harvested energy at each receiver. In order to achieve this target, we propose an iterative algorithm for allocating subcarriers to each user, allocating power to each subcarrier, and computing the optimal ratio of the received signal power that goes to the information decoder and the energy harvester. The second problem is the maximization of the total harvested energy under constraints on the minimum rate achieved by each user. We propose resource allocation and receive processing algorithms as in the previous case. Numerical results are provided, and the merits of the proposed design for various operating conditions and parameters are illustrated.**

I. Introduction

Simultaneous transmission of information and energy in wireless systems have received considerable attention recently [1], [2], [3]. Such techniques enable the receivers to perform both information decoding and energy harvesting from the same electromagnetic wave. The received energy is either used to operate the receiver circuit or stored for later use. Such energy harvesting techniques hold great potential for energy-constrained networks with limited energy storage capability. Over the years, the size of batteries used to drive the wireless devices has decreased considerably. Rapid drainage of these battery sources necessitate the devices to use battery optimally by compromising on other important tasks [4]. To complement the decreasing battery size, demand for efficient and compact energy harvesters (EHs) have grown many folds [5]. In this context, the wireless transmission of power along with information holds great promise.

Conventional receiver architectures have mainly focused on increasing the data rates. These optimal receivers used for information decoding are incapable of performing both *wireless information transfer* and *wireless energy transfer* simultaneously. Therefore, this calls for a change in the receiver architecture to support *simultaneous wireless information and energy transfer*. *Time switching (TS)* and *power splitting (PS)* are two practical receiver schemes proposed by researchers to address this problem [4], [5]. In TS, the receiver is designed in such a way that for a first few symbols, it harvests all the energy from the signal power while for the remaining symbols, all of the signal power is utilized for information decoding. However, in case of PS, a fraction of the received signal power is used for harvesting energy and the remaining power is used for decoding information simultaneously.

Orthogonal frequency division multiplexing (OFDM) is a spectrally efficient multi-carrier transmission technique and it has been widely adopted in many recent standards. However, the simultaneous information and energy transmission techniques in the context of OFDM have not been widely studied [4]. In conventional OFDM, subcarriers are assigned to the users based on two main resource allocation schemes: fixed [7] and dynamic [8], [9]. When incorporated with wireless energy transfer, OFDM not only preserves its existing advantages, but it also allows multiple devices to charge simultaneously using wireless recharging. A framework for OFDM-based architecture along with power control algorithms to exploit frequency diversity that improves information and energy transfer efficiency is considered in [1].

In this paper, we consider simultaneous transmission of information and energy in the downlink of a network that employs OFDM. We address the optimal resource allocation for maximizing the weighted sum of rates and for maximizing the total harvested energy. The receivers are assumed to employ PS scheme to decode information and harvest energy simultaneously. Optimal resource allocation, which can significantly enhance the performance of OFDM systems, is well-studied in the conventional use of OFDM. Optimal subcarrier and power allocation and receive processing is a challenging problem when the additional requirement of energy transmission is taken into account. To overcome this difficulty, we propose an iterative algorithm for joint subcarrier and power allocation at the transmitter and the optimal ratio of the received signal that goes to the information decoder and energy harvester at each receiver. The algorithms reported in [9] does not consider allocation of subcarriers to each user, whereas the algorithm proposed in this paper performs the subcarrier allocation as well.

The paper is organized as follows. Section II presents a description about the system model. Section III comprises of solutions to the proposed problems involving both maximization of transmit rate and harvested energy. Section IV

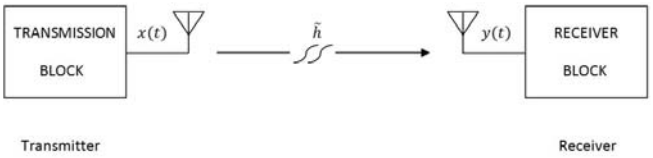

Fig. 1: System model

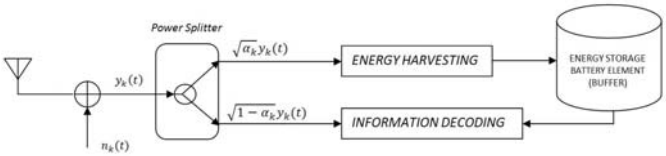

Fig. 2: Receiver architecture (for the kth user)

comprises of simulation results for the proposed algorithms. Finally, section V concludes the paper.

II. System Model

The system model considered in this paper consists of a transmitter that can transmit both information and energy to K users. Fig. 1 depicts a simple block schema of the overall model. It is considered that each user is capable of decoding information and harvesting energy simultaneously.

The transmitter considered in this paper consists of a single antenna. Let $x_k(t)$ denote the signal for kth user, η_k denotes minimum harvested energy constraint known to the transmitter, E_k is the energy harvested by kth user at the receiver and P_T denotes the total transmit power. A frequency selective fading channel is considered. Let H_k denote the channel gain matrix for the kth user, $h_{k,n}$ be the channel gain for kth user in the nth subcarrier, N_0 be the power spectral density (PSD) of additive white Gaussian noise (AWGN) and B be the overall available bandwidth in MHz range. The entire bandwidth is divided into N subcarriers and the power allocated to the nth subcarrier is denoted be p_n. Let K denote the total number of users where $k = 1, 2,..., K$. We assume that $x_k(t)$ is a narrow–band signal having a bandwidth of '$\frac{B}{N}$' MHz, and $\mathbb{E}[|x_k(t)|^2] = 1$ where $|.|$ denotes the absolute value or norm and $\mathbb{E}[.]$ denotes the statistical expectation for the kth user.

Consider a receiver model with single receiving antenna as shown in Fig. 2. Let the received signal to be denoted by $y_k(t)$ and receiver noise for kth user be denoted as $n_k(t)$. Here, the noise $n_k(t)$ can be modelled as a narrow-band Gaussian noise with bandwith equals '$\frac{B}{N}$' and centered around the frequency f_k. The complex equivalent of noise can be adopted from [5] as: $n_k = \sqrt{2}\Re\{\hat{n}_k(t)e^{j2\pi f_k t}\}$, where $\hat{n}_k(t) \sim \mathcal{CN}(0, \frac{\sigma_k^2}{2})$, where $\sigma_k^2 = N_o\left(\frac{B}{N}\right)$ which implies that $\hat{n}_k(t)$ is a circulary symmetric complex Gaussian (CSCG) RV with zero mean and variance σ_k^2.

The signal received at the kth user on the nth subcarrier can be expressed as

$$y_{k,n} = h_{k,n}x_{k,n} + n_{k,n} \tag{1}$$

At each receiver, a power splitter (PS) is employed so that an optimal fraction of the received signal is provided to the information decoder and the remaining part is provided to the energy harvester [5]. The PS ratio at the kth user is denoted by α_k, where $0 < \alpha_k \leq 1$. We can notice from Fig. 2 that PS plays a very important role in determining the efficiency of the receiver system.

Let R_k denote the kth user's rate expressed as:

$$R_k = \sum_{n \in \mathcal{S}_k} \log_2\Big(1 + (1-\alpha_k)p_n\gamma_{k,n}\Big), \tag{2}$$

where $\mathcal{S}_k$ is the set of subcarriers allocated to the kth user, and $\gamma_{k,n} = \frac{|h_{k,n}|^2}{\sigma_n^2}$. We also define

$$E_k = \alpha_k \sum_{n=1}^{N} p_n |h_{k,n}|^2. \tag{3}$$

It should be noted that each user can harvest energy from all the subcarriers.

III. Maximization of the sum-rate

We consider the problem of maximizing the weighted sum-rate of the users while ensuring that the energy harvested at each user is above a given threshold and the total transmit power does not exceed a given limit. To solve this problem, we require a mechanism that not only performs joint subcarrier and power allocation, but also find an optimal PS ratio, α_k, $k = 1, 2, \cdots, K$, at the receiver. The same α_k is applicable for all the subcarriers received by the kth user.

This problem $(P1)$ can be expressed as

$$(P1): \quad \max_{\{\alpha_k\},\{p_k\},\{\mathcal{S}_k\}} \quad \sum_{k=1}^{K} w_k R_k \tag{4}$$

$$\text{subject to}: \quad E_k \geq \eta_k, \tag{5}$$

$$\sum_{n=1}^{N} p_n \leq P_T, \tag{6}$$

where w_k is the weighting factor of the kth user's rate, η_k is the minimum energy harvested by the kth user, and P_T is the upper limit on the total transmit power. Obviously, this is a non-convex optimization problem. Since the solution to problem $(P1)$ involves joint optimization of subcarrier allocation and power, this is a mixed integer programming problem, therefore the possible solutions are not tractable. Hence, computing the optimal solution to this problem is very challenging. Therefore, we propose an algorithm to solve this problem iteratively.

The proposed algorithm (I) can be outlined as follows:

1) Initialize: $\mathcal{U} = \{1, 2, \cdots, K\}$, $\mathcal{S}_k = \phi$, $\alpha_k \in [0\ 1]$, $\Gamma_k = 0$, $k = 1, 2, \cdots, K$.
   Iterate over steps 2 to 5 until convergence
2) $\mathcal{V} = \{1, 2, \cdots, N\}$
3) for $k = 1$ to K,
   a) find n such that $|h_{k,n}| > |h_{k,m}|, \quad m, n \in \mathcal{V}$
   b) $S_k = S_k \cup \{n\}, \Gamma_k = \Gamma_k + \frac{P_T}{N}$
   c) $R_k = \log_2\left(1 + (1-\alpha_k)\Gamma_k\gamma_k\right)$
   d) $\mathcal{V} = \mathcal{V} - \{n\}$
4) While $\mathcal{V} \neq \phi$,
   a) find i such that $w_i R_i \leq w_k R_k$, $i, k \in \mathcal{U}$

b) for the i found in (4.a), find n such that $\gamma_{i,n} \geq \gamma_{i,l}$ $n, l \in \mathcal{V}$
c) $S_i = S_i \cup \{n\}$, Γ_i=Γ_i+ $\frac{P_T}{N}$
d) $\mathcal{V} = \mathcal{V} - \{n\}$
e) Use water-filling algorithm with $R_i = \sum_{n \in S_i} \log_2\big(1 + (1-\alpha_i)\Gamma_{i,n}\gamma_{i,n}\big)$ and $\sum_{n \in S_i} p_n = \Gamma_i$ to compute p_n, $\forall n \in \mathcal{S}_i$

5) Compute PS ratio $\alpha_k = \frac{\eta_k}{\sum_{\forall n} |h_{k,n}|^2 p_n}$, $\forall k \in \mathcal{U}$.

It should be noted that if $\alpha_k = 0$, then the receiver will not be able to harvest any energy at all. However, if $\alpha_k = 1$, all the power from the transmit signal can be harvested at the receiver. In step 5) of the algorithm, it is assumed that equality holds for the constraint in (5). It should be noted that the algorithm iteratively optimizes $\{p_n\}$ and $\{\alpha_k\}$, until convergence. (6) indicates that we can keep adding power until the equality is obtained, thereby maximizing the overall weighted sum rate. The proposed algorithm (I) is motivated by the resource allocation algorithm in [9], where energy transmission is not considered. In general, the subcarriers and power allocation is performed for K users involving N+K optimization parameters for an optimal solution. The proposed algorithm allocates power using water-filling for $(N-K)$ times along with the steps involved in [8].

IV. Maximization of the total harvested energy

In this section, we consider the problem of determining the optimal resource allocation and the PS ratio for maximizing the total energy harvested by the users under constraints on the rates available to each user and the total transmit power. Mathematically, this problem (P2) can be formulated as follows:

$$(P2): \max_{\{\alpha_k\},\{p_n\},\{\mathcal{S}_k\}} \quad \sum_{k=1}^{K}\Big(\alpha_k \sum_{n=1}^{N} p_n |h_{k,n}|^2\Big) \tag{7}$$

$$\text{subject to}: \quad \sum_{j \in \mathcal{S}_k} \log_2\Big(1+\Lambda_j\Big) \geq \rho_k, \ \forall k, \tag{8}$$

$$\sum_{i=1}^{N} p_i \leq P_T, \tag{9}$$

$$p_i \geq 0, \qquad \forall i, \tag{10}$$

$$0 \leq \alpha_k \leq 1, \qquad \forall k, \tag{11}$$

where $\Lambda_j = \frac{(1-\alpha_k)p_j|h_{k,j}|^2}{\sigma_j^2}$, $k = 1, 2, \cdots, K$, $i = 1, 2, \cdots, N$, the constant ρ_k is the minimum rate required by the kth user and the other variables have the same meanings as defined previously. Again, the solutions to problem $(P2)$ are not tractable as this is also a mixed integer problem involving joint subcarrier and power allocation as in the previous case. Therefore, we propose to solve this problem by alternatively computing $\{p_n\}$ for fixed values of $\{\alpha_k\}$, $\{S_k\}$ and vice versa.

Considering fixed values of $\{\alpha_k\}$ and $\{S_k\}$ to optimize $\{p_n\}$, we can rewrite the problem $(P2)$ as:

$$(P3): \max_{\{p_n\}} \quad \sum_{k=1}^{K}\Big(\alpha_k \sum_{n=1}^{N} p_n |h_{k,n}|^2\Big) \tag{12}$$

$$\text{subject to}: \quad \sum_{j \in \mathcal{S}_k} \log_2\Big(1+\Lambda_j\Big) \geq \rho_k, \forall k, \tag{13}$$

$$\sum_{i=1}^{N} p_i \leq P_T, \tag{14}$$

$$p_i \geq 0, \qquad \forall i, \tag{15}$$

where $k = 1, 2, \cdots, K$, $i = 1, 2, \cdots, N$, and other variables have same meanings as defined earlier. We can solve this problem using the *Karush-Kuhn-Tucker* (KKT) conditions for the optimal solution. The objective function and constraints can be written as:

$$f(\mathbf{p}) = \sum_{k=1}^{K}\Big(\alpha_k \sum_{n=1}^{N} p_n |h_{k,n}|^2\Big) \tag{16}$$

$$g_k(\mathbf{p}) = -\Big[\sum_{j \in \mathcal{S}_k} \log_2\Big(1+\Lambda_j\Big) - \rho_k\Big] \leq 0, \forall k, \tag{17}$$

$$r(\mathbf{p}) = (\sum_{i=1}^{N} p_i - P_T) \leq 0, \tag{18}$$

Using (16), (17), and (18), the Lagrangian is given as:

$$\mathcal{L}(\mathbf{p}; \lambda_k, \mu) = f(\mathbf{p}) + \sum_{k=1}^{K} \lambda_k g_k(\mathbf{p}) + \mu r(\mathbf{p}) \tag{19}$$

For optimality, $\nabla_{\mathbf{p}}\ \mathcal{L}(\mathbf{p}; \lambda_k, \mu) = 0$. Thus, we can represent the equation for satisfying optimality condition as:

$$\sum_{k=1}^{K} \alpha_k \sum_{n=1}^{N} |h_{k,n}|^2 + \sum_{k=1}^{K} \lambda_k g_k'(\mathbf{p}) + \mu = 0 \tag{20}$$

where $g_k'(\mathbf{p}) = -\sum_{j \in S_k}\Big(\frac{(1-\alpha_k)|h_{k,n}|^2}{\sigma_j^2 + (1-\alpha_k)p_j|h_{k,n}|^2}\Big)\frac{1}{ln2}$. The feasibility conditions can be represented as $g_k(\mathbf{p})$ and $r(\mathbf{p})$ which are expressed in (17) and (18). Complementary slackness expressions can be represented as follows:

$$\lambda_k\Big[\sum_{j \in \mathcal{S}_k} \log_2\Big(1+\Lambda_j\Big) - \rho_k\Big] = 0, \quad k = 1, 2, \cdots, K, \tag{21}$$

$$\mu\Big(\sum_{i=1}^{N} p_i - P_T\Big) = 0, \tag{22}$$

The conditions for non-negativity are: $p_j, \lambda_k, \mu \geq 0$. After further analysis, it is found that if $\lambda_k \neq 0$ and $\mu \neq 0$, then from (20) we can express p_j's as:

$$p_j = \mathcal{X} - \sum_{j \in S_k} \frac{\sigma_j^2}{(1-\alpha_k)|h_{k,j}|^2}, \forall j \in S_k, \tag{23}$$

where $\mathcal{X} = \frac{\lambda_k}{\left(\sum_{k=1}^{K}\alpha_k \sum_{n=1}^{N}|h_{k,n}|^2+\mu\right)ln2}$ and $k = 1, 2, \cdots, K$. The values for λ_k's can be expressed using (20) as follows:

$$\lambda_k = \frac{\left(\sum_{k=1}^{K}\alpha_k \sum_{n=1}^{N}|h_{k,n}|^2\right)ln2}{\sum_{j\in S_k}\left(\frac{(1-\alpha_k)|h_{k,n}|^2}{\sigma_j^2+(1-\alpha_k)p_j|h_{k,n}|^2}\right)} \tag{24}$$

The value of μ can also be obtained using (20).

Similarly, considering fixed values of $\{p_n\}$ and $\{S_k\}$ to optimize $\{\alpha_k\}$, we can reduce the problem $(P2)$ as follows:

$$(P4): \quad \max_{\{\alpha_k\}} \quad \sum_{k=1}^{K}\left(\alpha_k \sum_{n=1}^{N} p_n|h_{k,n}|^2\right) \tag{25}$$

$$\text{subject to}: \quad \sum_{j\in\mathcal{S}_k}\log_2\left(1+\Lambda_j\right) \geq \rho_k, \forall k, \tag{26}$$

$$0 \leq \alpha_k \leq 1, \qquad \forall k, \tag{27}$$

where $k = 1, 2, \cdots, K$. This is a separable problem, and hence it can be decomposed into K independent problem as follows:

$$(P5): \quad \max_{\{\alpha_k\}} \quad \alpha_k \sum_{n=1}^{N} p_n|h_{k,n}|^2, \tag{28}$$

$$\text{subject to}: \quad \sum_{j\in\mathcal{S}_k}\log_2\left(1+\Lambda_j\right) \geq \rho_k, \tag{29}$$

$$0 \leq \alpha_k \leq 1, \tag{30}$$

In order to solve this problem, we can apply line search algorithm using strong Wolfe conditions [10].

Thus, to solve the proposed problem $(P2)$, following should be repeated till desired convergence: (*i*) perform subcarrier allocation(S_k), (*ii*) solve $(P3)$ for fixed values of $\{\alpha_k\}$ and $\{S_k\}$, and (*iii*) solve $(P4)$ for fixed values of $\{p_n\}$ and $\{S_k\}$. The proposed algorithm (II) can be outlined as:

1) Initialize: $\mathcal{U} = \{1, 2, \cdots, K\}$; $\mathcal{S}_k = \phi$; $\alpha_k \in [0\ \ 1]$; $\mathcal{V} = \{1, 2, \cdots, N\}$; $\Gamma = \{p_n\}, \forall n \in \mathcal{V}$; $j = 0$; $\{g\} = \{h\}$.
2) $q_i = \sum_{\forall i}|g_{i,n}|, \quad i \in \mathcal{U}$ and $n \in \mathcal{V}$
3) Perform the following steps to obtain initial power in each subcarrier using $\{q\}$ obtained from 2):
   a) $\sum_{\forall i} q_i p_i = q^T\Gamma, \quad i \in \mathcal{V}$
   b) $\epsilon = \frac{P_T}{\sum_{\forall i} q_i}, \quad i \in \mathcal{V}$
   c) Find an optimal $\{\Psi\}$ for sub–carriers: $\Psi = \epsilon q$
   d) $\hat{g}_{k,n} = 0, \mu_k = \phi, \forall k \in \mathcal{U}$ and $\forall n \in \mathcal{V}$

   Repeat steps 4 to 6 until convergence
4) for $i = 1$ *to* N
   a) find n such that $g_{n,i} \geq g_{m,i}$, $n,m \in \mathcal{U}$
   b) increment j by 1 and set $\tilde{g}_{n,i} = g_{n,i}$ and $g_{n,i} = 0$
   c) if $\mu_j = \phi$ then $\mu_j = \mu_j + \{n\}$
      else if $\mu_j \neq \phi$ and $n \in \mu_j$, then find n again using 4(a) and 4(b) till $n \notin \mu_j$
   d) $\hat{g}_{n,i} = |\sqrt{1-\alpha_i}\tilde{g}_{n,i}|, \quad \forall i \in \mathcal{U}$
   e) if $\log_2(1+\hat{g}_{n,i}\Psi_i) \geq \rho_j$, then $\mathcal{S}_n = \mathcal{S}_n + \{i\}$
   f) if $j = K$, then set $j = 0$ and $\mu_k = \phi$, $\forall k \in \mathcal{U}$

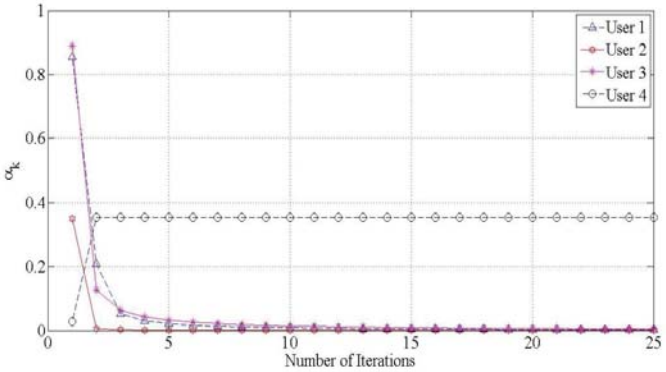

Fig. 3: Convergence of PS ratio α_k for K=4 users with $N = 256$ subcarriers and $B = 1$ MHz.

5) Fix $\{\alpha_k\}$ and $\{\mathcal{S}_k\}$ to maximize (7) over $\{p_i\}$ under the constraints (8), (9) and (10) until convergence, $\forall k \in \mathcal{U}$ and $\forall i \in \mathcal{V}$. $(Ref: (23))$
6) Fix the optimized Γ obtained, along with $\{\mathcal{S}_k\}$, to maximize (7) over $\{\alpha_i\}$ under the constraints (8) and (11) until convergence, $\forall i,k \in \mathcal{U}$. $(Ref: (28))$

In the algorithm above, step 3) is used to initialize the power of each subcarrier. It turns out that when the objective function obtains its maxima, the equality in (9) always holds. To see that, observe that if the current allocated power does not add upto the upper limit, we can always increase the power until the limit is reached without violating the rate constraint. From steps 5) and 6), we can infer that the solution to problem $(P2)$ can be found using divide and conquer mechanism by splitting $(P2)$ into two sub-problems $(P3)$ and $(P4)$ [corresponding to steps 5) and 6) respectively], and then applying the KKT conditions as described previously. The algorithm is operational for (N+K) times over a single iteration and therefore, the order of this algorithm can be expressed as a linear function of N and K for all the iterations.

V. SIMULATION RESULTS

In this section, we evaluate the performance of the two proposed algorithms using simulations. We consider $N = 256$ OFDM subcarriers, total bandwidth $B = 1$MHz, and N_0=-90dBW/Hz throughout the simulations where each user has 6-tap sample-spaced multipath channel with each tap experiencing independent Rayleigh fading. The weights w_i, $i = 1, 2, \cdots, K$ are all set to one. The lower limit of the harvested energy (η) is assumed to be the same for all users.

Fig. 3 illustrates the convergence of PS ratio (α_k) over the indicated iterations. It can be observed from results in Fig. 3 that the PS ratio (α_k), obtained from the proposed algorithm (I) converges to the optimum value within around 20 iterations for all considered scenarios. Fig. 4 depicts the performance of proposed algorithm (I) in terms of spectral efficiency, where it is compared with equal power allocation algorithm (EPA) for K=8 users with different values of total transmit power (P_T). The result indicates that maximum spectral efficiency is obtained when minimum demanded harvested energy (η) is 0 dBm. However, it can be observed that the spectral efficiency

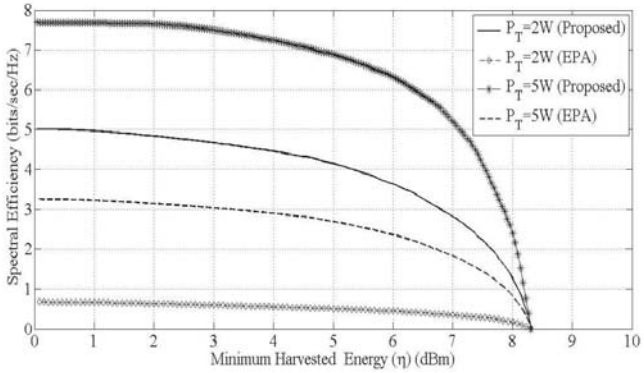

Fig. 4: Spectral efficiency versus minimum harvested energy requirement (η) for K=8 users with different P_T values.

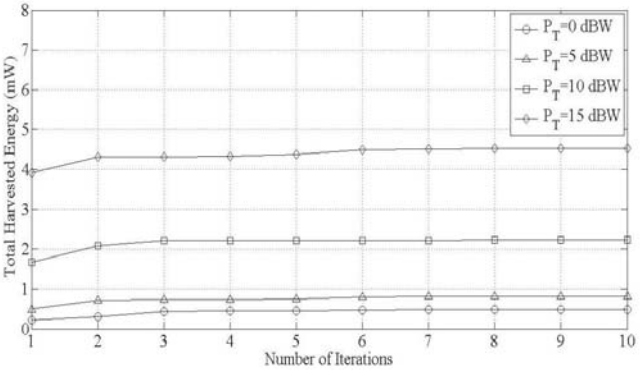

Fig. 5: Total Harvested Energy (in mW) versus number of iterations for K=4 users with different P_T values (in dBW).

is found to decrease as the demand for harvested energy is increased. It can also be noted that the spectral efficiency improves considerably as P_T increases.

In Fig. 5, performance of algorithm (II) is shown where the convergence of total harvested energy (in mW) is seen over different iterations for K=4 users and different values of P_T (in dBW). From the results, it can be observed that total harvested energy (in mW) in proposed algorithm (II) converges to the optimum value within 10 iterations for all the scenarios considered. Again, the fast convergence of proposed algorithm (II) confirms its practical implementations. Fig. 6 shows the average maximized harvested energy $\{\xi_{avg}\}$ by average rates $\{\rho_{avg}\}$ demanded by K=4 users for different P_T values. The maximized harvested energy (E_k^*) is calculated using (3) for all the K users. The average maximized harvested energy is given as, $\xi_{avg} = \frac{\sum_{\forall k} E_k^*}{K}$, $k = 1, 2, \cdots, K$. For simplicity, uniform rates (ρ_{avg}=10 Mbits/s) were considered for all the users during simulations. From the results it can be seen that, as the values of P_T increases, ξ_{avg} increases appreciably. It can be observed from Fig. 6 that ξ_{avg} decreases with increasing values ρ_{avg}.

VI. CONCLUSIONS

In this paper, multiuser OFDM environment is considered for transmission. It is assumed that channel conditions are known to both the transmitter and the receiver. Considering

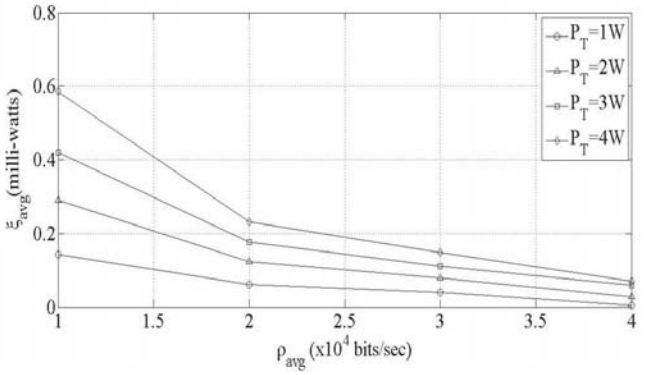

Fig. 6: Average maximized harvested energy (ξ_{avg}) versus average rate (ρ_{avg}) for K=4 users with different P_T values.

the users' frequency selective nature of the channels, we performed joint subcarrier and power allocation along with computation of a power splitting ratio, α_k. In this process, transmit rate should be kept maximum, without compromising the QoS. At the receiver, we use a power splitter (PS) for splitting the received signal power for energy harvesting and information decoding using the α_k value at the transmitter. Then, the harvested energy is maximized for each user under the constraints on minimum known rate and total transmit power. Proposed algorithm (I) is compared with equal power allocation algorithm. Moreover, it is seen that the harvested energy at energy harvester is maximized using our approach from proposed algorithm (II). This work can further be extended to many fascinating directions like addressing the design of PS, formulating an optimal approach to maximize harvested energy, and exploiting the diversities originating from time varying channels.

***Abstract*—With an estimation of 20 billion devices being connected to the Internet in the coming years, the accuracy and the robustness of the wireless communication modules takes the center stage. The health-care scenario, due to its critical nature, calls for an error free communication. IEEE 802.15.4 is the established standard in the Internet of Things scenario that uses Direct Sequence Spread Spectrum - Offset Quadrature Phase Shift Keying (DSSS-OQPSK) modulation. In this paper, we propose a modified minimal error IEEE 802.15.4 communication system for the IoT applications in health care. The proposed architecture uses Maximum Likelihood based frequency offset estimator that can compensate upto 80ppm of the frequency offset. The detection of the symbols is achieved by the complex correlation of the spread sequence. The Bit Error Rate (BER) performance of the proposed architecture is significantly improved compared to the standard architecture. For example, at BER of 0.01, it achieves a gain of 2db over the standard. The proposed ML estimator for frequency offset performs better in terms of error variance than the existing estimators for IEEE 802.15.4.**

I. Introduction

Internet of things (IoT) provides gateways to many industrial and medical applications. Healthcare applications such as patient monitoring using Body Area Networks (BAN) is being developed in IoT. Since IoT enabled devices usually transmit data on a wireless channel, there is requirement of transmitting the data such as electrocardiogram, blood pressure, temperature with less errors. Also, most of the IoT enabled devices are battery powered so the system we choose should consume less power. Healthcare includes various patient monitoring data such as Electrocardiogram (ECG), blood pressure, body temperature etc.

ECG conveys information about heart like heart rate and heart rhythm. All heart related diseases like convective heart failure, heart attack and other diseases can be diagnosed by analyzing the changes in ECG pattern. ECG signal has few key features, the PR, QRS and ST intervals that conveys critical information regarding the condition of the patient. The P wave gives information regarding the atrial contraction. The QRS interval represents the conductance and depolarization of the ventricles. The ST segment shows the time period in which the ventricles are isoelectric. There have been many wearable wireless ECG systems developed. In [1], an ECG, EEG, respiration rate and motion monitoring healthcare system was developed using IEEE 802.15.4 as communication standard. For acquiring ECG data, we have used Adaptive Rule Engine based Data Acquisition system developed at IITH [2]. Our data acquisition system has 3 lead ECG that requires 4 electrodes connected to the body.

For wireless ECG data transmission ZigBee, Wi-Fi, Bluetooth technologies have been used in the literature. In [3], the Bluetooth module has been used as an intermediate node between ECG acquisition module and smart phone in ECG monitoring system. In [4] a Wi-Fi based system with a single-chip ECG acquisition module on Concerto MCU, a simpleLink CC3000 Wi-Fi module and a smart phone was used. In [5], IEEE 802.15.4 module has been used to transmit ECG data. For our work, we are concentrating on transmission of ECG data whose maximum frequency can be 200Hz which requires minimum sampling rate of 400 samples/sec. If the resolution of the data is maintained at 16 bits, then the data rate of the ECG would be 6.4Kbps, which makes it suitable for IEEE 802.15.4 transmission which can handle upto data rate of 250Kbps. The IEEE 802.15.4 standard can be adopted for its low cost effectiveness, low power consumption and reliable self configurable capability which is the prime requirement of the ECG signal transmission.

In an IoT and WSN scenario, a node can transmit data at any time making it a random access network. The fixed preamble helps in identifying the valid IEEE 802.15.4 packet and the start of the payload. The transmitted packet format of IEEE 802.15.4 is shown in the Fig. 1, in which it has fixed preamble of length 32 bits. This preamble is used for carrier and frame synchronization.

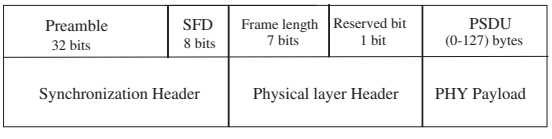

Fig. 1: IEEE 802.15.4 PHY Packet Format

Synchronization is an essential task at the baseband receiver. The received signal needs to be operated on the same clock as that of the transmitter. But in practice, oscillators differ slightly in the frequency they generate, thus creating a frequency offset at the receiver. The indoor channel effects also contributes to this offset. Frequency offset in IEEE 802.15.4

may range from 8ppm to 80ppm thus causing a maximum offset of 200KHz. The received signal may also be out of phase resulting in the phase offset. Significant amount of work is done in the field of synchronization. In [6], data aided ML estimator for joint synchronization of frequency, phase and timing offsets is used. This work is done on a preamble sequence of alternating zeros and ones that are BPSK modulated. But in IEEE 802.15.4, the baseband receiver will receive a 256 bit spreaded sequence resulted from a 32 bit preamble of all zeros. Hence, the simplifications derived from an alternating zeros and ones cannot be employed here. In [7], a simple and low complex frequency offset estimator using correlation for IEEE 802.15.4 receiver is proposed. But their estimator performance shows a significant gap between their error variance and Cramer Rao Lower Bound (CRB) for frequency estimators. In this paper we propose a joint ML estimator for phase and frequency offset working on the spreaded sequence of the preamble. The performance of the proposed estimator is significantly closer to the CRB.

Frame synchronization is achieved through correlation of the received preamble with the fixed preamble sequence. If the correlator output crosses a threshold, the packet is detected as a valid packet. In [8], authors have shown that differential encoding reduces the false and missing probabilities in Packet Detection for BPSK Signals. The authors in [9] have analyzed the packet detection with differential encoding for IEEE 802.15.4 and have shown that this method provides robust packet detection. Our receiver architecture employs symbol detection method used in [10] that correlates the received complex samples with a set of reference complex samples resulting in lesser BER.

The rest of the paper is organized as follows, the proposed architectures of transmitter and receiver are discussed under section II. The simulation results is under section III and Section IV concludes the paper with future scope.

II. Proposed System Architectures

We propose an ASIC(Application Specific Integrated Circuit) based on-chip architecture for ECG monitoring as shown in Fig.2. The System Architecture for the transmission and reception of ECG data is shown in Fig. 3. The transmitter and receiver blocks are explained in detail in the following subsections.

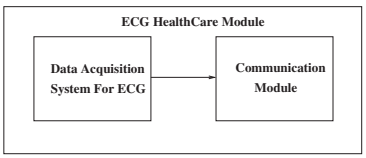

Fig. 2: ASIC chip Architecture

A. IEEE 802.15.4 Transmitter

The proposed transmitter structure is as shown in Fig. 4. The analog ECG signal is passed through the ADC in the data acquisition system and the digital output is at 500 samples/sec. This bitstream is differentially encoded as shown

$$y_k = x_k \oplus y_{k-1}$$

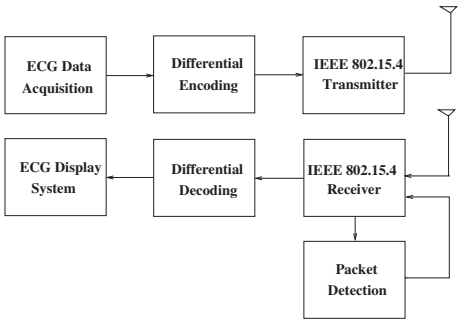

Fig. 3: Overall System Architecture

y_0 is taken as 0 at the start of the packet. The encoded bits which are at a rate of 250Kbps are mapped to symbols in the Bit to Symbol block with each symbol equivalent to 4 bits. Each symbol is mapped to a fixed 32 bit chip sequence using Direct Sequence Spread Spectrum (DSSS). These chip sequences are inherently orthogonal to each other. The output of this symbol to chip block has a data rate of 2Mbps. The signal is now modulated by using the Offset Quadrature Phase Shift Keying (OQPSK) modulation whose in-phase and out-phase component will be at a rate of 1Mbps. Each component is passed through a half sine pulse shaping filter to limit the bandwidth of the signal.

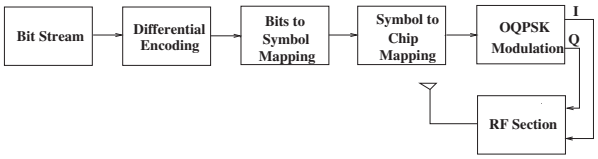

Fig. 4: IEEE 802.15.4 Transmitter with Differential Encoding

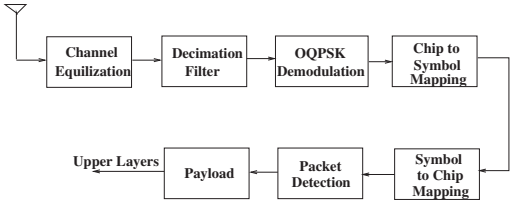

Fig. 5: IEEE 802.15.4 Receiver for ECG Data Transmission

B. IEEE 802.15.4 Receiver

1) Standard IEEE 802.15.4 Receiver: A standard receiver architecture is shown in the Fig. 5. The received signal, at the input of the baseband is filtered to remove the out of band noise. If the channel is incorporated, then corresponding equalization will be done with the help of pilot carriers. The signal is decimated and then demodulated by the OQPSK demodulation block and the chip to symbol and then symbol to bit mapping is done. The payload of the packet is detected

by the packet detection algorithm which is done by cross correlation with the fixed sequence which is 32 bit zeros. If the correlation is above the threshold value, then the payload is send to the post processing block for further processing.

2) Proposed IEEE 802.15.4 Receiver: The proposed architecture as shown in figure 6 uses a ML frequency estimator and a correlation and estimation block.

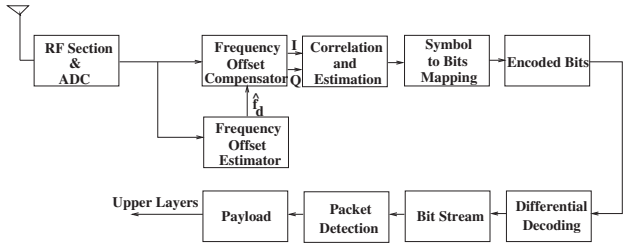

Fig. 6: Proposed IEEE 802.15.4 Receiver for ECG Data Transmission

Maximum Likelihood based carrier frequency and phase offset estimation:
The carrier frequency offset (f_d) and phase offset (θ) are manifested in the received baseband signal ($z(t)$) as:

$$z(t) = exp(j(2\pi f_d t + \theta))s(t) + n(t) \tag{1}$$

where
$s(t)$: Modulated signal $s(t) = \sum_i c_i g(t - iT_c)$
c_i is a complex symbol and g(t) is the half sine pulse shape.
T_c is the symbol period after DSSS
$n(t)$: Gaussian Noise with zero mean and variance σ_n^2

The preamble used in IEEE 802.15.4 standard contains 32 bits of zeros that corresponds to eight symbols of the integer value 0. These eight symbols each have fixed 32 bit spread sequence of $[11011001110000110101001000101110]$. This gives a spreaded sequence of length 256 bits that maps to 128 OQPSK symbols. This fixed sequence helps in data aided synchronization.
The ML estimation uses the modulated signal $s(t)$ derived from these known sequences.

The log likelihood function for the unknown carrier offset as given in [11] is:

$$\Lambda_l(\tilde{f_d}, \tilde{\theta}) = Re\left\{\left[\int_{T_0} z(t)s^*(t : \tilde{f_d}, \tilde{\theta})e^{(-i(2\pi \tilde{f_d} t + \tilde{\theta}))}dt\right]\right\} \tag{2}$$

$s(t)$: Known modulated signal of the spread sequence of the preamble.
$z(t)$: Received signal.
$\tilde{f_d}$: Frequency offset estimate.
$\tilde{\theta}$: Phase offset estimate.
The discrete time equivalent of the equation (2) when sampled at $t = kT_c/2N$, that is at twice of the chip frequency is:

$$\Lambda_l(\tilde{v}, \tilde{\theta}) = Re\left\{\left[\sum_{k=0}^{N_0-1} z[k]s^*[k]e^{(-i(\pi \tilde{v} k + \tilde{\theta}))}\right]\right\} \tag{3}$$

where
N_0 is the number of times the sequence is sampled.
$k = 0, 1, 2, 3, ...$
$\tilde{v} = \tilde{f_d} Tc/N_0$, the normalized carrier frequency offset

Rearranging the equation (3) gives :

$$\Lambda_l(\tilde{v}, \tilde{\theta}) = Re\left\{\left[e^{-i\theta}\sum_{k=0}^{N_0-1} z[k]s^*[k]e^{(-i(\pi \tilde{v} k))}\right]\right\} \tag{4}$$

Let us define

$$\Delta(\tilde{v}) = \sum_{k=0}^{N_0-1} z[k]s^*[k]e^{(-i(\pi \tilde{v} k))} \tag{5}$$

Then equation (4) becomes

$$\Lambda_l(\tilde{v}, \tilde{\theta}) = Re\{[e^{-i\tilde{\theta}}\Delta(\tilde{v})]\} \tag{6}$$

The value of $\tilde{\theta}$ that maximizes the likelihood function is given as:

$$\tilde{\theta} = arg\{\Delta(\tilde{v})\} \tag{7}$$

Now, define $q[k] = z[k]s^*[k]$
Equation (5) becomes

$$\Delta(\tilde{v}) = \sum_{k=0}^{N_0-1} q[k]e^{-i(\pi v k)} \tag{8}$$

As clearly seen, equation (8) takes the form of a Discrete Fourier Transform (DFT). The value of $\tilde{v}$ can be derived from maximizing $\Delta(\tilde{v})$.

$$\tilde{v} = max\left\{\sum_{k=0}^{N_0-1} q[k]e^{-i(\pi v k)}\right\} \tag{9}$$

The DFT can be performed efficiently using an N-point Fast Fourier Transform (FFT). The accuracy of the estimated value $\tilde{v}$ depends on the resolution of the FFT performed. The signal q[k] is zero padded to perform high resolution FFT that generates accurate value of $\tilde{v}$.

Correlation and Estimation block:

The baseband received signal passed through the channel can be expressed as:

$$z(i) = \sum_{\tau=0}^{L} h(\tau)s(i - \tau) + n(i) \tag{10}$$

where
$z(i)$: Received Signal
$s(i)$: Modulated Signal
$n(i)$: Gaussian Noise with zero mean and variance σ_n^2
$h(\tau)$: τ-th coefficient of the channel

$$h(\tau) = a(\tau)e^{j\theta(\tau)}$$

The channel is a Complex Gaussian distribution whose amplitude and phase follows Rayleigh and Uniform distributions respectively with L+1 taps.

For the k-th received signal, the correlator output is

$$J_k(l) = \sum_{n=0}^{15} |z(i)g^*(l,n)|^2$$

$$= \sum_{n=0}^{15} |g^*(l,n) \sum_{\tau=0}^{L} h(\tau)s(i-\tau)|^2 \quad (11)$$

where g(l,n) is the n-th sample of the l-th symbol's complex half sine modulated signal. Since the Gaussian noise is independent of the modulated signal, the correlation between noise and the modulated signal goes to zero.
The expectation of the output gives

$$E\{J_k(l)\} = \begin{cases} 16\sigma_g^2 \sum_{\tau=0}^{L} |h(\tau)|^2, n = i-\tau \\ 16\sigma_{xy}^2 \sum_{\tau=0}^{L} |h(\tau)|^2, n \neq i-\tau \end{cases} \quad (12)$$

where,
$\sigma_g^2 = E\{|g(l,n)|^2\}, l = k$

$\sigma_{xy}^2 = E\{g^*(l,n)g(k,n)\}, l \neq k$

The symbol can be hence estimated as:

$$\hat{l}_k = argmax_l\{J_k(l)\} \quad (13)$$

that is, the reference signal that gives maximum correlation with the received signal in the symbol duration is the estimated symbol. The flow of the block is shown in figure 7. Thus, the correlation and estimation block outputs an estimated symbol, eliminating the need of despreading. The estimated symbol is then mapped to corresponding four bits which are then differentially decoded and the payload is extracted.

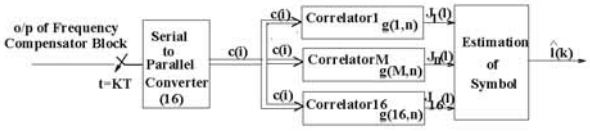

Fig. 7: Correlation and Estimation Block

III. Performance Analysis

The analysis of the proposed architectures is done with the described ECG data acquisition system. The packet is constructed with 32 bits preamble and 127 bytes of payload coming from the ECG data acquisition system. The simulation is done for 500 packets with SNR ranging from -10dB to 5dB. The architecture is analyzed under the conditions of AWGN Channel.

A. ECG signal reconstruction

The transmitted ECG signal is shown in figure 8. AWGN channel is considered. The proposed architecture faithfully recovers the ECG signal under these conditions without any loss in the features at 0dB SNR as shown in the figure.

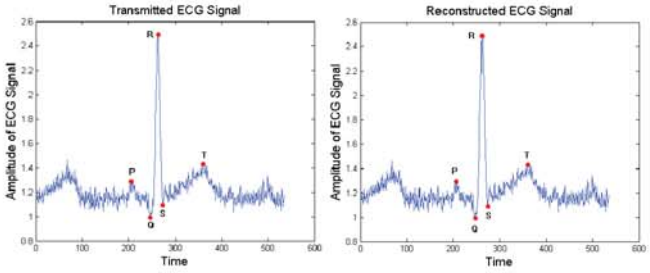

Fig. 8: Transmitted and Received ECG Signal through AWGN

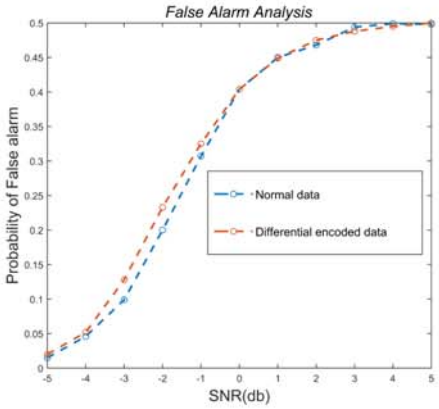

Fig. 9: Probability of False Alarm Analysis

B. Probability of False Alarm Analysis

The probability of miss and false alarm with differential encoded data for IEEE 802.15.4 was studied in [12]. It was proposed that differential encoded data performs better than the normal data. The variation probability of false alarm with SNR for both types of data for the proposed architecture is plotted in figure 9. It can be seen that the results for the normal data is as good as that of differential encoded data. This is due to the better error management of the correlation and estimation block in the proposed architecture.

C. Frequency Estimator Analysis

The Error variance of the proposed estimator is plotted in 10. The Cramer Rao Lower Bound (CRB) for the variance of a frequency offset estimator is given in [7] as:

$$var(\delta f) = 3(2\pi^2 E_b/N_0 T_c^2 N(N^2-1))^{-1}$$

where
N: sequence length
E_b/N_0: SNR in linear scale
T_c: chip interval

The simulations has been done by considering an offset of 80ppm that is approximately 200KHz which is the maximum offset in IEEE 802.15.4. As seen in figure 10, with the increase in FFT resolution, the error variance of the proposed estimator approaches the CRB. This is due to the increase in accuracy of the estimated value. We have also plotted the error variance of the estimator proposed in [7] for IEEE 802.15.4. This results shows that the performance is better than the estimator of [7] with a trade off in complexity.

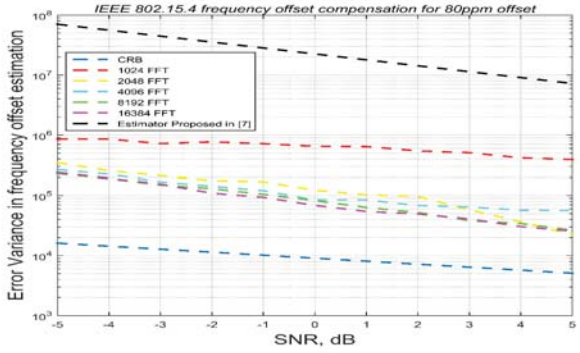

Fig. 10: Error Variance compared with CRB for 80ppm frequency offset

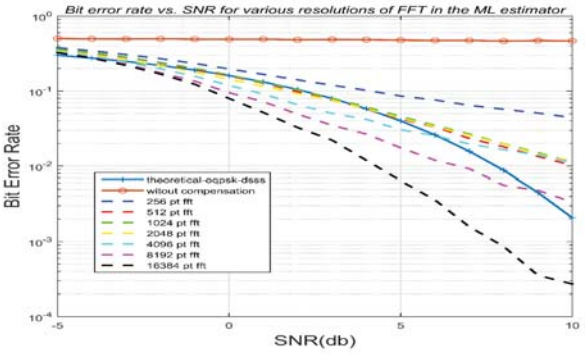

Fig. 11: Comparison of BER for different resolutions of FFT

D. BER Analysis

BER analysis as shown in figure 11 shows that the error performance has been significantly improved when compared to that of standard architecture. It has been analyzed without frequency offset compensation and with compensations under various resolution of Fast Fourier Transforms(FFT) used in the estimator. It is observed that with the increase in the resolution the BER performance significantly improves. At 512 point FFT which is relatively less complex to design, the BER performance matches with the theoretical OQPSK-DSSS BER given in [13] at low SNRs. It can be seen that the estimator with 8192 point FFT has a gain of 2db at BER of 0.01 while 16384 point FFT has more than 5db gain. This error performance is achieved due to complex correlation used for detection and accurate compensation for the frequency offsets. It is also observed that the frequency offsets, if not compensated degrades the performance severely. The frequency offset estimator improves the performance effectively even at the 80ppm of frequency offset.

IV. Conclusion

In this paper we proposed a minimal error communication module and has been tested for ECG data. The ECG signal from the data acquisition system is transmitted and faithfully reconstructed at the receiver. The proposed receiver performs considerably better than the standard architecture in terms of BER. The proposed frequency offset estimator eliminates the frequency offsets effectively and achieves error variance closer to the variance of Cramer Rao Bound. The use of correlation and estimation block eliminates the need for a despreading block which makes our system less erroneous.

***Abstract*—Accurate relay node model for a generic topology of multi-hop networks is still unsolved problem in the Wireless Sensor Networks (WSN) arena. Even though there are lot of multi-hop models in the literature, there is still a lot of scope for improvement in these relay node models to achieve end-to-end reliability and delay optimizing energy. In this paper a state behavioural relay node model is developed integrating IEEE 802.5.4 MAC and energy conserving states like Sleep, Idle-Listen and Active-Tx using three dimensional Markov chain framework. Novel window of reference is introduced into relay nodes to decide the wake up strategies and to improve performance of the network. Hence developed model is a combination of asynchronous and periodic protocols which is first in it's kind of nature. Developed emulation model of the MAC confirms the performance improvement with 95% confidence level. Analysis proves that random anycast routing with proposed duty cycle model extends network lifetime with efficient load sharing among all relay nodes and reduce overall active duration of a node.**

***Keywords*-Anycast clustered multi-hop network, 3D Markov chain, Analytical model of IEEE 802.15.4 MAC.**

I. Introduction

Multi-hop communication is essential for real time applications like IoT, Cyber Physical Systems (CPS) and Smart grid applications which are distributed over large area. Most of the IEEE 802.15.4 analytical models are based on 3D Markov chains. Single-hop IEEE 802.15.4 networks has been thoroughly investigated, but analytical model that can mimic multi-hop networks is still under active research.

IEEE 802.15.4 multi-hop models are inspired by IEEE 802.11 multi-hop networks in [1], [2] and [3]. Multi-hop communication is modelled for IEEE 802.11 networks for single traffic flow in [1]. Work in [1] has been extended to multiple non saturated flows in [2]. A model for saturated traffic flows in IEEE 802.11 networks is presented in [3]. However, we note that these models cannot be directly applied to IEEE 802.15.4 networks due to the different access mechanisms of IEEE 802.11 and IEEE 802.15.4. Analytical modelling of IEEE 802.15.4 multi-hop network is discussed in [4] considering heterogeneous traffic and hidden node terminal problem. Model presented in [4] analysed multi-hop considering different topologies. Even though model captured multi-hop behaviour for particular topologies due to route layer dependencies analysing a larger network without a generalized model becomes complex. Reliable and timely communication for sensors to sink is discussed in [5] with anycast multi-hop routing between relay clusters. Reliability, delay and energy of overall network are analysed with cumulative exponential wake up rate, traffic rate and number of relay clusters. Model in [5] proposed different states like sleep, idle, active and CSMA/CA for relay nodes but analytical model has fixed backoff window and lacks many network parameters.

Carrier sense multiple access with collision avoidance (CSMA/CA) scheme MultiCSMA for multi-hop WSNs is proposed in [6]. A Markov chain based analytical model for multi-hop networks is analysed with variation in traffic rate, node density, packet length, number of MAC backoff stages and retries are considered for the analysis. An analytical model for evaluating the performance of IEEE 802.15.4 multi-hop networks based on beacon-less CSMA/CA is discussed in [7]. Multi-hop tree network with sensors and relay nodes (relay node can be sensors as well) considering with and without hidden node problem was analysed in [7]. Though model in [7] captured tree multi-hop network behaviour but nodes nearer to sink have higher congestion leading to failure of nodes as well as network failure. Most of the above mentioned models could not capture multi-hop behaviour in the aspects like relay hot spots and failed to obtain generalized analytical model with network parameters like wake up rate, packet rate, packet length and node density. Above mentioned problems are answered in this paper proposing a route independent anycast routing based modified IEEE 802.15.4 analytical model. Beacon enabled slotted IEEE 802.15.4 standard is modified to model a generalized relay node in a cluster between a sensor/source node to central sink node. Relay node is modelled with three dimensional Markov chain with states like sleep, idle, active and IEEE CSMA/CA states to obtain tradeoff between application performance and energy savings.

The remainder of this paper is as follows. In Section II, proposed system model is described. Mathematical model of the proposed system is given in detail in Section III. Analytical and simulation results of proposed system is discussed in section IV. Finally, Section V concludes the paper with future scope of research.

II. System Model

We consider a generic network scenario of central sink with sensor and relay clusters shown in the Fig. 1. Sensors are distributed across large area, where data from them is forwarded using relay cluster nodes. Relay nodes in each cluster can accept data from any node and any direction in the neighborhood and forwards to it's nearest neighbor cluster which is well known as anycast routing. Relay node behaviour is captured accurately in 4 different states namely, Sleep (S_i), Idle-Listen (I_i), Active-Tx (A_i) and CSMA/CA as shown in Fig. 2. Relay node state behavioural model is briefly described as below.

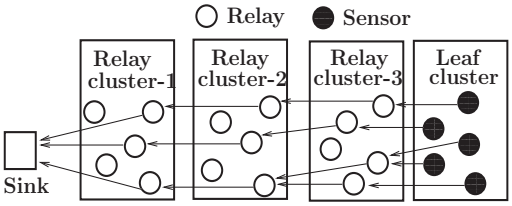

Fig. 1: Example network scenario of the proposed system

Relay node after every S_0 slot moves to Idle-Listen state with P_w probability or rolls back to Sleep state shown in the Fig. 2. Relay node after successful transition to Idle-Listen state with probability P_w waits for LI_{avg} slots to observe a packet from preceding cluster. Time intervals between beacons observed by a relay in Active-Tx are poisson distributed which determine the average waiting time LA_{avg} slots in Active-Tx state. Relay node which is successful in receiving a beacon within maximum L_a slots of Active-Tx state follows CSMA/CA flow depicted using a 3D Markov chain shown in Fig. 3 with backoff stages (*m*), backoff counter (*k*) and collision retries (*n*) as the three dimensions. Relay node spends an average LC_{avg} slots in CSMA/CA state. Finally node spends $L_{S|CSMA}$ slots in Sleep which are the remaining slots left after Idle-Listen, Active-Tx and CSMA/CA states.

Total number of slots that a relay node takes to complete all states is fixed as L_{DC}, which we termed as Duty cycle window or frame of reference window. It is assumed that only one wake-up can happen with a P_w probability, where P_w is the provability of a node to have a wake-up in first slot of L_{DC} from $1/L_{DC}$ poisson distributed wake-ups in a second. Relay node cannot wake-up in between L_{DC} slots and transmit beacon. It is also evident from above assumption that relay node can only service one packet in L_{DC} slots. The maximum capacity of a relay cluster *C* is $\frac{N}{L_{DC}}$. If number of packets to the relay cluster is more than capacity of network, then network performance surely degrade.

III. Mathematical model

We first define the required terminologies for the mathematical model and then follows the formulation of CSMA/CA model. In the rest of our discussion μ_w indicates average wake up rate per node in a cluster consisting of *N* nodes, L_a and L_i are length of active and idle slots respectively.

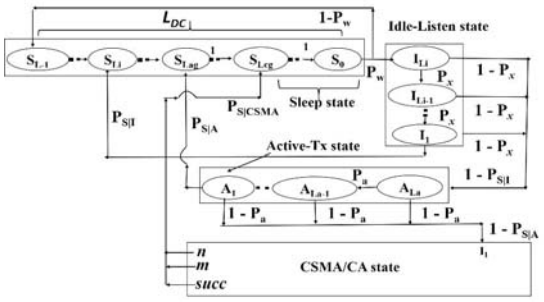

Fig. 2: Relay node model with Duty cycle frame work

In Eq. 2 , P_x gives the transition probability of a relay node to move into next Idle-Listen slot from the current, when there is no packet arrival at a given slot with an average of λ poisson arrivals and P_a in Eq. 4 indicates the transition probability of a relay node to move into next Active-Tx slot from the current, when there is no beacon arrival at a given slot with an average of λ_a poisson arrivals. The probability of a node transiting to Sleep state from last slot of Idle-Listen ($P_{S|I}$), Active-Tx ($P_{S|A}$) and CSMA/CA ($P_{S|CSMA}$) states can be obtained as shown in Eq. 13, 14 and 12 respectively.

$$\lambda_a = \mu_w * L_{DC} \tag{1}$$

$$P_x = \exp(-\lambda) \tag{2}$$

$$P_w = 1 - \exp(-\lambda_a) \tag{3}$$

$$P_a = (1 - \frac{P_w}{L_{DC}})^N \tag{4}$$

$$LA_{avg} = \sum_{i=1}^{L_a} (i) \frac{P_a^{i-1}(1-P_a)}{(1-P_a^{L_a})} \tag{5}$$

$$LI_{avg} = \sum_{i=1}^{L_i} (i) \frac{P_x^{i-1}(1-P_x)}{(1-P_x^{L_i})} \tag{6}$$

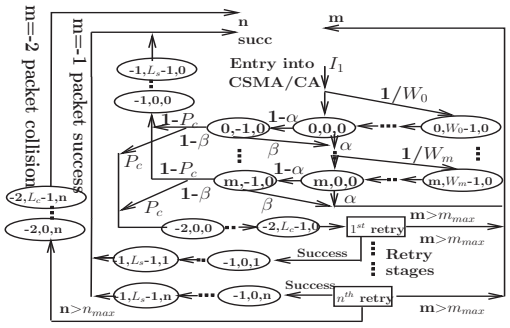

Fig. 3: 3D Markov model of IEEE 802.15.4 CSMA/CA

Relay node with proposed cyclic state framework is shown in Fig. 2. Relay node state transition starts from last slot S_{L_0} and moves to Idle-Listen state with P_w probability or rolls back to Sleep state with 1-P_w probability. P_w is the probability of a node to have a wake-up at the first slot of L_{DC} window, where wake-up of a node is assumed Poisson process with mean μ. Relay node wake-up at first slot is considered because

node is assumed to complete all its states with in L_{DC} slots and no wake-up is possible after first slot of L_{DC} window. Relay node which is wake-up at first slot follows similar Idle-Listen, Active-Tx and CSMA/CA state behaviour in the model already described. If a relay node is unsuccessful in receiving a packet it spends its rest of time in Sleep state shown in Eq. 7. Relay node after successfully receiving a packet and failing to receive a beacon in Active-Tx spends rest of time in Sleep state shown in Eq. 8. Relay node which is successful in Idle-Listen and Active-Tx states completes its CSMA/CA state in LC_{avg} which is shown in Eq. 10 and the time it spends in Sleep state after CSMA/CA is shown in Eq. 9. LC_{avg} is the average number of slots a node spends in CSMA/CA assuming CSMA/CA as gaussian distribution.

$$L_{S|I} = L_{DC} - L_i \tag{7}$$

$$L_{S|A} = L_{DC} - LI_{Avg} - L_a \tag{8}$$

$$L_{S|CSMA} = L_{DC} - LI_{Avg} - LA_{avg} - LC_{avg} \tag{9}$$

$$LC_{avg} = \frac{(n+1)(m+1)W_0}{2} \tag{10}$$

where, W_0 is the minimum backoff window (2^{m_0}), *m* is the maximum backoff stages and *n* is the maximum collision retries. It is observed that from the above expressions that relay node spends remaining time in Sleep state after it completes Idle-Listen, Active-Tx and CSMA/CA states. It is also evident that $L_{S|CSMA}$ should not exceed L_{DC} as the window size is fixed. In order to conserve energy, node should spend more time in Sleep state by adjusting other state parameters LI_{avg}, LA_{avg} and LC_{avg} considering given constraints. State probabilities and state transition probabilities of relay node with proposed framework is given in detail as below.

State transition probabilities are derived observing state behaviour model of relay node with framework shown in Fig. 2. $P_{S_{L_{DC}}}$ is the probability of a node to be in first slot of duty cycle window. $P_{S|I}$, $P_{S|A}$, $P_{S|CSMA}$ and $P_{S|L_{DC}}$ are the probabilities of a node to enter Sleep state from Idle-Listen, Active-Tx, CSMA/CA and last slot of Sleep state respectively. Expressions inter relating these probabilities are given below. P_{S_0} is the probability to enter in last slot of Sleep state.

$$P_{S_0} = P_{S|CSMA} \tag{11}$$

$$P_{S|CSMA} = P_{S|A} + b_{0,0,0} \tag{12}$$

$$P_{S|A} = P_{S|I} + P_a^{L_a} P_{A_0} \tag{13}$$

$$P_{S|I} = P_{S|L_{DC}} + P_i^{L_i} P_{I_0} \tag{14}$$

$$P_{S|L_{DC}} = (1 - P_w) P_{S_0} \tag{15}$$

$$P_{S_0} = (1 - P_w) P_{S_0} + P_x^{L_i} P_w * P_{S_0} + P_a^{L_a} (1 - P_i^{L_i}) P_w * P_{S_0} + Z_0 * b_{0,0,0}^f \tag{16}$$

Rearranging the Eq. 16, we arrive at an expression relating P_{S_0} and $b_{0,0,0}^f$. P_x and P_a are failure probabilities to receive a packet and beacon in any slot of Idle-Listen and Active-Tx states respectively from their neighbor cluster nodes. State provability equations for Sleep, Idle-Listen, Active-Tx and CSMA/CA are given in Eq. 17, 18, 19 and 20 respectively.

$$L_i * P_{S|L_{DC}} + L_a * P_{S|I} + L_c * P_{S|A} + L_{S|CSMA} P_{S|CSMA} = P_S \tag{17}$$

$$P_I = \frac{P_w * P_{S_0} * (1 - P_x^{L_i})}{1 - P_x} \tag{18}$$

$$P_A = \frac{P_w * P_{S_0} * (1 - P_x^{L_i})(1 - P_a^{L_a})}{1 - P_a} \tag{19}$$

$$P_{CSMA} = b_{0,0,0}^f * Z_1 \tag{20}$$

After substituting the above state probabilities in normalization property of Markov chain shown in Eq. 21, we can arrive at essential Markov probability $b_{0,0,0}^f$.

$$P_S + P_I + P_A + P_{CSMA} = 1 \tag{21}$$

In this paper busy channel probabilities α and β in Clear Channel Assessment (CCA1 and CCA2) states and channel sensing probability τ shown in Fig. 3 are derived considering the effect of Cyclic states Sleep, Idle-Listen and Active-Tx state probabilities along with CSMA/CA model. With basic understanding of busy probabilities in [8], [9], [10] and [11] one can derive easily $b_{0,0,0}^f$ and thereby α, β and τ using numerical methods. End-to-end Reliability, delay and energy of the proposed multi-hop model for dense traffic applications are derived in next section using mathematical expressions in previous section.

A. End-to-end Reliability Model

Performance metrics for leaf to relay cluster and end cluster to gateway cluster differ from relay to relay cluster link. All these three different links are modeled separately as follows.

$$P_f^A = \frac{P_w * (1 - P_x^{L_i}) * (1 - P_a^{L_a}) * P_{S_0}}{1 - P_a} \tag{22}$$

$$P_f^a = P_a^{L_a} \quad , P_f^m = x^{\mathrm{m+1}}(1 + \widetilde{y}) \quad , P_f^n = \widetilde{y}^{\mathrm{n+1}} \tag{23}$$

Reliability of leaf to relay link is given in Eq. 24. Reliability is derived by deriving failure probabilities of this link. Failure can happen due to channel access failure and collisions in CSMA/CA state. Packet is also discarded when leaf node cannot find a beacon in L_a slots.

$$R_S = 1 - \left(P_f^m + P_f^n + P_f^a + P_f^A\right) \tag{24}$$

$$R_k = 1 - \left(P_f^m + P_f^n + P_f^a\right) \tag{25}$$

Reliability of link between end and gateway node is shown in Eq. 26. Reliability of this link is obtained by considering CSMA/CA failure probabilities. End node doesn't have Active-Tx state due to which failure is only due to CSMA/CA is shown in the Eq. 26.

$$R_G = 1 - \left(P_f^m + P_f^n\right) \tag{26}$$

Above three links are assumed independent as shown in

Eq. 27 to obtain end-to-end performance metrics. 3D Markov modeling is used to model all three different state models.

$$R_E = R_L * \prod_{k=1}^{h} R_k * R_G \tag{27}$$

B. Delay model

End-to-end delay of the proposed model is summation of delay incurred at three types of links, shown in Eq. 28.

$$D_T = D_{SR} + \sum_{i=0}^{h} D_R(i) + D_{EG} \tag{28}$$

where D_{SR} is the delay of link between sensor and first relay cluster, $D_R(i)$ is the delay of a link between two relay nodes, D_{EG} is the delay of the link between end node and gateway/sink node. Delay models for each link are expressed in mathematical expressions and finally an end-to-end delay of the network is derived in following section.

1) Delay between Sensor and Relay: Delay of this link is composed of CSMA/CA delay and Active-Tx state delay. CSMA/CA delay of a link with *N* nodes in a cluster is similar to [11] shown in Eq. 29. Active-Tx state delay of the link is given in Eq. 30.

$$D_{\text{csma}} = (Ts + Delay_{\text{avg}}) \left(1 + \frac{y}{1-y} - \frac{(n+1) * y^{\text{n+1}}}{1-y^{\text{n+1}}}\right) \tag{29}$$

Sensor node in Active-Tx state waits for L_a consecutive slots to observe a beacon from next cluster. Sensor node may not wait for all L_a slots every time it enters Active-Tx state. Average number of slots a relay node waits to receive a beacon is the delay incurred in Active-Tx state. Broadcast of beacons from relay nodes in next cluster are Poisson distributed with mean λ_a. Active-Tx state delay D_{active} is shown in Eq. 30. Finally End-to-end delay (D_T) is sum of D_{csma} and D_{active} shown in Eq. 32. D_{SR} is shown in Eq. 31.

$$D_{active} = \sum_{i=1}^{L_a} (i) \frac{P_a^{i-1}}{\sum_{k=0}^{L_a} P_a^k} \tag{30}$$

$$D_{SR} = D_{\text{csma}} + D_{\text{active}} * S_b \tag{31}$$

D_{csma} shown in Eq. 29 is similar for relay-relay and end-gateway links. Relay-relay node link experience Active-Tx state delay as sensor node, but end-gateway link doesn't have Active-Tx state delay because gateway nodes in gateway cluster are always on to receive a packet. Relay node experience *h* number of Active-Tx state delays assuming node distribution in each relay cluster is same. End-to-end delay of the multi-hop network is shown in Eq. 32.

$$D_T = (h+2)D_{csma} + D_{active}(h+1) \tag{32}$$

C. Energy model

Energy of leaf, end and relay node models differ according to the state behaviour explained above. Energy of each node is derived from its state probabilities. State energies of leaf, end and relay nodes are calculated by accounting state transitions of each node. E_i, E_a, E_{CCA}, E_w, E_t and E_r are energy consumption in Idle-Listen, Active-Tx, CSMA/CA sensing, wake-up, transmit and receive state respectively.

1) Energy model - Leaf node: Energy spent by a leaf node can be derived considering state behaviour. Leaf node doesn't have Idle-Listen and receive states. Total energy of leaf node E_{leaf} is given in Eq. 33.

$$E_{leaf} = (E_a + E_w) + E_{\text{CCA}} + E_t \tag{33}$$

2) Energy model - End node: Energy spent by a end node is in Idle-Listen, CSMA/CA sensing, transmit and receive energies. End node Active-Tx energy is negligible as the gateway node is continuously on to receive a packet from end node. Total energy of end node E_{end} is given in Eq. 34.

$$E_{end} = (E_i + E_w) + E_{\text{CCA}} + E_t + E_r \tag{34}$$

3) Energy model - Relay node: Energy spent by a relay node can be derived by observing its state behaviour. Relay node state probabilities are derived in previous section. Total energy of leaf node E_{relay} is given in Eq. 35. Finally total energy is summation of all above node energies.

$$E_{relay} = (E_i + E_a + E_w) + E_{CCA} + E_t + E_r \tag{35}$$

IV. Analytical results

End-to-end reliability, delay and energy versus λ_g is plotted in Fig. 4(a), 4(b) and 4(c) respectively. λ_g is varied from 0.04 to 0.1 packets per slot probability. Reliability is also observed with variation in two different number of nodes in each cluster. Reliability is observed decreasing with traffic density and after certain increase in traffic variation, it decreases marginally. Increase in number of nodes from *N*=20 to 30 reduces reliability from 0.73 to 0.62 is shown in Fig. 4(a). Delay is increased marginally from 89 to 94 milliseconds with λ_g, when number of nodes are twenty. Increase in delay is justified by the fact that number of nodes increase the number of contending nodes for the channel resulting in increase in channel access delay of CSMA/CA. Energy increases with increase in λ_g due to increase in active time of relay nodes. Increase in number of nodes also increases energy as number of nodes participate in forwarding the traffic increases. Observing the plots Fig. 4(a), 4(b) and 4(c), it is observed that reliability, delay and energy respond to λ upto some extent and saturates to a value. This is due to same reason that after certain traffic levels reliability, delay and energy of networks doesn't change because the number of packets that receives with change in λ_g freezes to a value. Simulation and analytical results are in agreement with less than 4% mean error.

Congestion probability α, $b_{0,0,0}$ and Active state failure probability are observed with variation in λ_g and number of nodes in Fig. 4(d), 4(e) and 4(f) respectively. Increase in packet arrivals results in increase in α and $b_{0,0,0}$. Active state failure probability is nearly a constant value with increase in λ_g but when the number of nodes increased from 20 to 30, active failure probability reduces due to increase in number

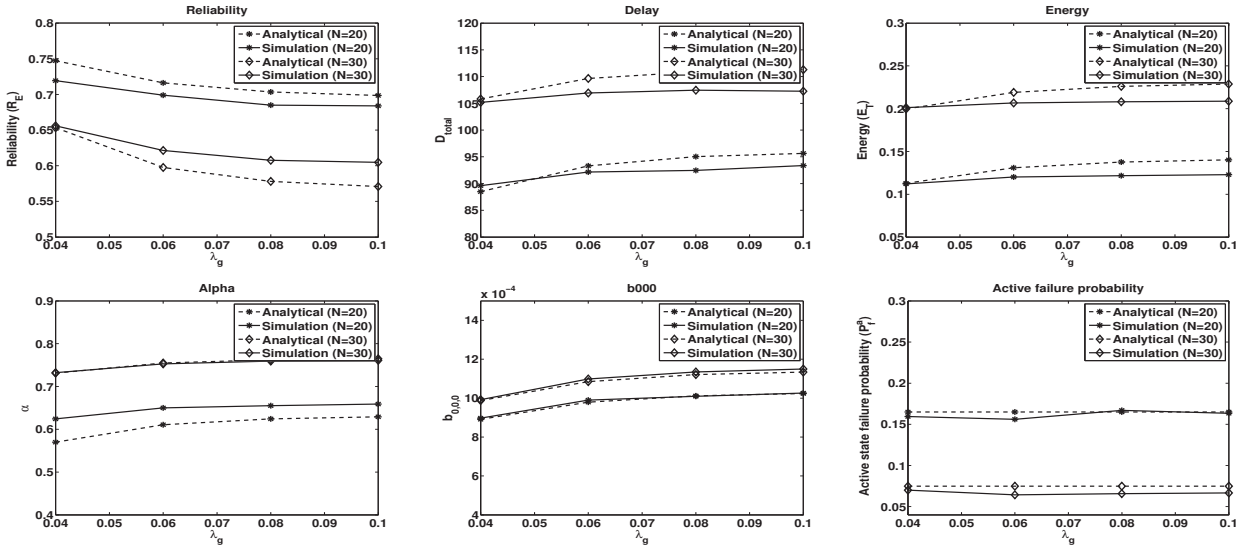

Fig. 4: Different performance metrics like R_E, D_T, E, α, $b_{0,0,0}$ and P_f^A variation with respect to λ_g and N; Fixed MAC and network parameters m_0 = 3, m = 4, L_{DC} = 500, μ_w = 6, n = 1, L_a = 70, N=[20 30], λ =[0.04 0.1], L_p = 30, L_i=100.

of beacons in L_a slots. In order to improve the performance metrics either N or μ of each relay node should be increased.

Energy of a relay node is also observed in terms of active duty cycle of relay node. Active states of a relay node are Idle-Listen, Active-Tx, CSMA/CA channel sensing, transmit and receive states. Proposed model active duty cycle is compared with existing multi-hop protocol in [5]. Results of comparison is given in Fig. 5. Parameters considered for the simulation are μ =4, N=15, m_0=3, m = 4 and n=3, L_i = 50 backoff slots, L_a = 70 backoff slots and each iteration is $4*10^5$ backoff slots. It is observed that proposed framework reduces duty cycle of nodes to 1.4%. It is observed that duty cycle of relay node is 60% lower on an average compared to the existing Breath model. Increase in energy savings is due to accurate state behaviour and anycast routing.

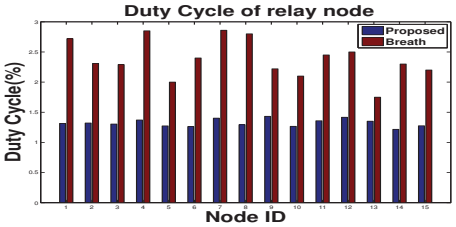

Fig. 5: Comparison of proposed and Breath models relay node duty cycle: N = 15, λ = 15 pks/sec, L_{DC} =700 slots, μ = 4

V. Conclusion

Three dimensional Markov model based analytical model for a relay node in a dense wireless multi-hop network is developed that can be part of IoT applications. Energy conserving state behaviour and generic anycast routing is integrated to IEEE 802.15.4 MAC. Results of the developed analytical and simulation models agree with each other with an accuracy of 5%. Active duty cycle of relay node is found 1.4% which is 60% less than existing models. Optimization framework at sink considering MAC and network parameters is the future scope of this work.

***Abstract*—This paper proposes broadband mesh network to operate in TV White Space (TVWS). Ad-hoc mode to extend IEEE 802.11af is designed to realize it. Prototype devices are implemented and field experiments using the devices in three practical scenarios are conducted. Experiment results show the feasibility of broadband mesh network operating in TVWS and that around one third of single hop throughput was achieved in two hop path. This paper also discusses deployment in large area with higher transmission power.**

Keywords— TV white space, Mesh network, Ad-hoc mode, Field experiment, IEEE 802.11af

I. INTRODUCTION

TV White Space (TVWS) is expected to expand available spectrum band for IP communications. Characteristics of the TV band include less attenuation over the air and much diffraction against obstacles compared with higher frequency bands which are much more often used for wireless broadband communications. Utilization of the TVWS can not only enhance spectrum utilization efficiency, but also increase flexibility and performance of wireless systems.

Specifications and radio regulations for TVWS that have been developed, such as IEEE 802.11af, IEEE 802.22 and FCC/Ofcom regulations [1-3], focus on perfect management of interference in order not to affect the TV broadcasts that are primary users. Therefore, basic concept of system is that White Space Database (WSDB) manages the interference from White Space Devices (WSDs) to TV broadcasts. It is required that a WSD register its GPS location to the WSDB and requests for available channels and transmission power before starting its operation. In this model, WSDs are managed centrally. The Access Point (AP) or Base Station (BS) which has interface with WSDB must exist in a network. Hence, since the WSDB is operated in the Internet, it is difficult to realize infrastructure-less or self-organized networks operating in TVWS such as point-to-point or mesh network. However, demands for such types of wireless networking are increasing recently to deploy broadband Internet to rural area or islands with less population where optical fiber network operators are reluctant to extend their business due to cost. Such networks could be possible to be realized under certain conditions of regulations. Mesh network is a typical self-organized and infrastructure-less network. Mesh network operating in TVWS will create technically new applications. Also, it is helpful in emergency situations such as recovery of networking after disasters.

Existing specifications for wireless LAN in 2.4/5 GHz allows ad-hoc network for point-to-point (P2P) connection. Moreover, IEEE 802.11s realizes mesh networking of wireless LAN. However, the link distance is limited up to several hundred meters even in good conditions. Also, there are regulations and products for long-distance P2P connection in microwave band. But, they require sharp directional antenna, therefore are not flexible. Its system becomes complicated and total cost to configure multi-hop networks is very expensive. If TVWS is used to mesh networks, the networks can be flexible, low-cost and extendable to new applications.

In this paper, we propose a broadband mesh network operating in TVWS by extending IEEE 802.11af, develop prototype system, and conduct field experiments to measure the throughput in practical scenarios.

II. MOTIVATION AND RELATED WORKS

In mesh networks, one node establishes multiple links with other nodes at the same time. This is because of topology of mesh network. As long as the topology is not daisy chain connection, some nodes must have multiple links. Another reason is that nodes have backup links which are switched to active link in case when current active link is disconnected. Fig. 1 shows a timing to switch to use a backup link as active link. The solid lines are active links and dotted line is a backup link. In the beginning, Node 3 and Node 4 established a link as backup. When the link between Node 2 and Node 4 was disconnected, the backup link becomes active.

There are two basic approaches in assignment of frequency (or channel) to links of mesh networks. The first approach is to assign different channels to different links. The second approach is to assign the same channel to all the links. The first approach require multiple channels and functions to assign them efficiently. Merit of this approach is that transmission in each link does not interfere with other links or, even when the number of available channels are not sufficient for the links, the interference can be reduced to a certain extent. However, each node of mesh networks needs to operate on multiple channels to establish links with other nodes each of which is operated in different channels. Therefore, the device needs to have rich hardware specifications for multiple channel operation resulting in complicated, large in size, and expensive devices compared with the second approach.

The second approach shares a common channel with all the nodes of a mesh network. The ad-hoc mode in IEEE 802.11

adopts this approach. Merit of this approach is that limited frequency band is not split into pieces, therefore maximum capacity of each link is kept large. Establishment of multiple links is managed in Media Access Control (MAC) layer, hence its hardware should be capable of operation in a single channel. Management of channel assignment to links are not required. However, there are issues of performance deterioration due to transmission timing such as the hidden node problem and the procedure of Carrier Sense Multiple Access / Collision Avoidance (CSMA/CA). This paper takes the second approach to elaborate the limited TVWS channel utilization.

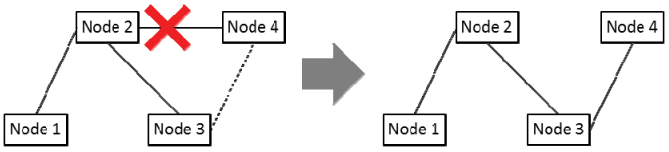

Fig. 1. Back up link in mesh networking

Major standards for wireless network system operating in TVWS are IEEE 802.11af and IEEE 802.22 [4-5]. In addition, LTE system operating in TVWS is proposed [6]. IEEE 802.11af is composed of Access Point (AP) and Station (STA). It does not assume connections between APs nor connections between STAs, therefore mesh networking is difficult with this standard. IEEE 802.22 is composed of Base Station (BS) and Consumer Premise Equipment (CPE) and has the same issue as in IEEE 802.11af to realize mesh network. LTE system is composed of evolved NodeB (eNB) and User Equipment (UE). The eNB needs to exchange management signals with Evolved Packet Core (EPC) which is typically managed carefully in a machine room and accessed via stable wired network. Therefore, LTE system is not appropriate for mesh networking.

Regarding the regulations on TVWS operation, devices are categorized into two types. One type of device needs to access the WSDB to register its location and obtain available channels, which is called Fixed or Mode II device in FCC's regulation and master device in Ofcom' regulation [1-3]. The other type of device must be under the control of the first type of devices, which is called Mode I device in FCC's regulation and slave device in Ofcom's regulation. In mesh networks, each node needs to transmit beacons so that other nodes find its existence. Therefore, all the nodes in mesh network need to be Mode II or master device. But, the nodes are not necessarily always accessible to the WSDB. The nodes must have a way to access WSDB via other wireless systems, or the regulations need to be amended to support the concept of mesh networks. How to address these issues is out of the scope of this paper.

III. Proposal to Realize Mesh Network in TV White Space

A. Approach to realize ad-hoc mode in IEEE 802.11af

IEEE 802.11af specifies specification of wireless LAN operating in TVWS. But, it has only the infrastructure mode and it is impossible that any two nodes connect each other. To realize the point-to-point (ad-hoc) connection in IEEE 802.11af, functional requirements are summarized as follows. IEEE 802.11af has two types of devices; AP and STA, but only STAs are operated in the ad-hoc mode.

- Modify MAC to conduct active scan and disable passive scan (Note that IEEE 802.11af STA does not transmit any frames without reception of Beacon from APs.)
- Modify MAC to send back Probe Response on reception of Probe Request
- Modify MAC to send back Association Response on reception of Association Request
- Remove the interface to the WSDB and implement an interface to manually configure operation frequency

B. Implementation of TVWS mesh network system

Based on the functional requirements in previous section, architecture and functions of white space device are designed. The architecture is shown in Fig. 2. The device is an integration of SDR board and CPU board. The SDR board has Field-Programmable Gate Array (FPGA) in which IEEE 802.11af PHY and low-MAC are implemented. The CPU board is operated by Linux. SDR driver is a Linux kernel module to deal with the SDR board. The mac80211 is an open source kernel module extended to have IEEE 802.11af and the functional requirements. The wpa_supplicant is also open source kernel module and manages the PHY/MAC. The use land program "olsdr" is an implementation of Optimized Link State Routing (OLSR) [7] which is a routing protocol designed for mobile ad hoc networks. OLSR configures IP routing table appropriately so that traffic from any node can reach any destination nodes via other nodes. When the device is started, it searches other devices and try to establish links with them. Then, IP routing is configured using OLSR. Overview of the developed device is shown in Fig. 3.

Fig. 3. A TVWS device for TVWS mesh network

IV. Fundamental Performance Test

This section describes setup and results of fundamental performance test of the developed devices in a laboratory environment. The purpose of this test is to understand basic behavior of the multi-hop network performance with proposed extension to IEEE 802.11af.

Before the test in multi-hop configuration, sensitivity and maximum throughput were measured for different Modulation Coding Schemes (MCSs). As a result of measurements, the sensitivity was -89 dBm and -76 dBm in MCS 0 (BPSK, r=1/2) and 7 (64QAM, r=5/6), respectively. The maximum throughput was 1.45 Mbps and 6.21 Mbps in MCS 0 and 7, respectively. Note that the throughput was measured using iperf tool in UDP

mode. The throughput is averaged over 60 seconds of transmission with transmission data rate of 1500 kbps.

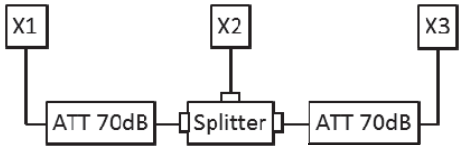

Fig. 4. System configuration of multi-hop networking for fundamental performance test

TABLE I. THROUGHPUT AND RSSI OVER RF CABLE

Direction / Link	From left to right (→)	From right to left (←)
X1-X2	870 kbps (-69 dBm)	1350 kbps (-73 dBm)
X2-X3	1450 kbps (-73 dBm)	1320 kbps (-71 dBm)
X1-(X2)-X3	328 kbps	468 kbps

Next, in order to test in the multi-hop environment, system was configured as shown in Fig. 4. X1, X2 and X3 are devices developed as described in section III. X1 and X3 are connected to the splitter via 70 dB of attenuator. There is a certain attenuation in the splitter between the two ports connected to X1 and X3. Output TX power and MCS were set to -3 dBm and 0 (BPSK r=1/2), respectively. As the sensitivity of the devices is around -89 dBm with this settings, X1 and X3 can not establish a link and X2 needs to relay both the links X1-X2 and X2-X3. The center frequency was 671 MHz (46 ch).

Table I shows throughput and RSSI for each link/path and traffic direction. The traffic direction from left to right on link X1-X2 is a direction from X1 to X2, whereas the direction from right to left on the same link is a direction from X2 to X1. Measurements were taken in two single links of X1-X2/X2-X3 and one multi-hop path X1-(X2)-X3 for both the traffic directions. The RSSI is shown in parentheses and was measured on the reception side of the traffic.

Throughput in single links (X1-X2 and X2-X3) were from 870 to 1450 kbps. Throughput in multi-hop (X1-X2-X3) was from 328 to 468 kbps. The multi-hop throughput is one third of the single link throughput. This is because the same spectrum band is shared with the two links and in addition some overhead due to the contention management of 802.11 MAC is in X2 to relay traffic over the two links.

Note that the reason why the RSSI are different in different directions and in different links is because the TX power is slightly different depending on individual device hardware. Also, due to the same reason, the throughput is partly not necessarily proportional to RSSI.

V. FIELD EXPERIMENTS

A. Environment and setup

Three scenarios are assumed for field experiments. The whole scenarios were set up at Yokosuka Research Park (YRP), Yokosuka, Japan. As shown in Fig. 5, seven points (A1-A4 and B1-B3) were specified as locations of nodes. In Fig. 5, lines in yellow are links between nodes. Numbers in yellow on the lines are the distance between the nodes. Numbers in white are altitudes above the sea at each location. Photos in red frames are taken from the locations of noted nodes.

Scenario 1 is the case where two nodes (A1 and A3) need to communicate, but they are not in line of sight due to big buildings, hence another node (A2) relays them. Scenario 2 is the case where two nodes (A2 and A4) need to communicate, but can not directly communicate due to long distance, hence another node (A3) relays them. Scenario 3 is the case where two nodes (B1 and B3) need to communicate, but they are two distant and also completely not in line of sight, hence another node (B2) on the roof of 25m height building relays them.

The devices and antennas were installed on cars except for B2, as shown in the right-top photo in Fig. 5. The antenna was mounted on the roof on cars. For B2, the device was set in a room of the building and its antenna was mounted on its roof, where the device and antenna were connected with RF cable of 50m length. Antennas are a whip type with 0 dBi gain except for B2 and co-linear type with 4.5 dBi for B2. Cable loss between the devices and antennas are 6 dB for B2 and 1.5 dB for the others, respectively.

Measurement tool and its settings are the same as described in section IV. The operation frequency, TX output power, and MCS were set to 671 MHz in center (46 ch), -3 dBm, 0 (BPSK r=1/2), respectively.

B. Measurements and discussions

The measurements of the three scenarios were conducted on July 21-22, 2015. For each scenario, it was confirmed that the target two nodes can not establish a direct link without a relay node. Measured throughput and RSSI in scenario 1 to 3 are shown in Table II (a) to (c), respectively. The notation of Table II is the same as in Table I.

TABLE II. THROUGHPUT AND RSSI IN FIELD EXPERIMENTS

(a) Scenario 1 (A1-A2-A3)

Direction / Link	From left to right (→)	From right to left (←)
A1-A2	951 kbps (-71 dBm)	1310 kbps (-71 dBm)
A2-A3	906 kbps (-77 dBm)	1090 kbps (-75 dBm)
A1-(A2)-A3	348 kbps	386 kbps

(b) Scenario 2 (A2-A3-A4)

Direction / Link	From left to right (→)	From right to left (←)
A2-A3	906 kbps (-77 dBm)	1090 kbps (-75 dBm)
A3-A4	152 kbps (-78 dBm)	277 kbps (-77 dBm)
A2-(A3)-A4	136 kbps	226 kbps

(c) Scenario 3 (B1-B2-B3)

Direction / Link	From left to right (→)	From right to left (←)
B1-B2	238 kbps (-80 dBm)	1240 kbps (-79 dBm)
B2-B3	235 kbps (-88 dBm)	235 kbps (-86 dBm)
B1-(B2)-B3	95 kbps	168 kbps

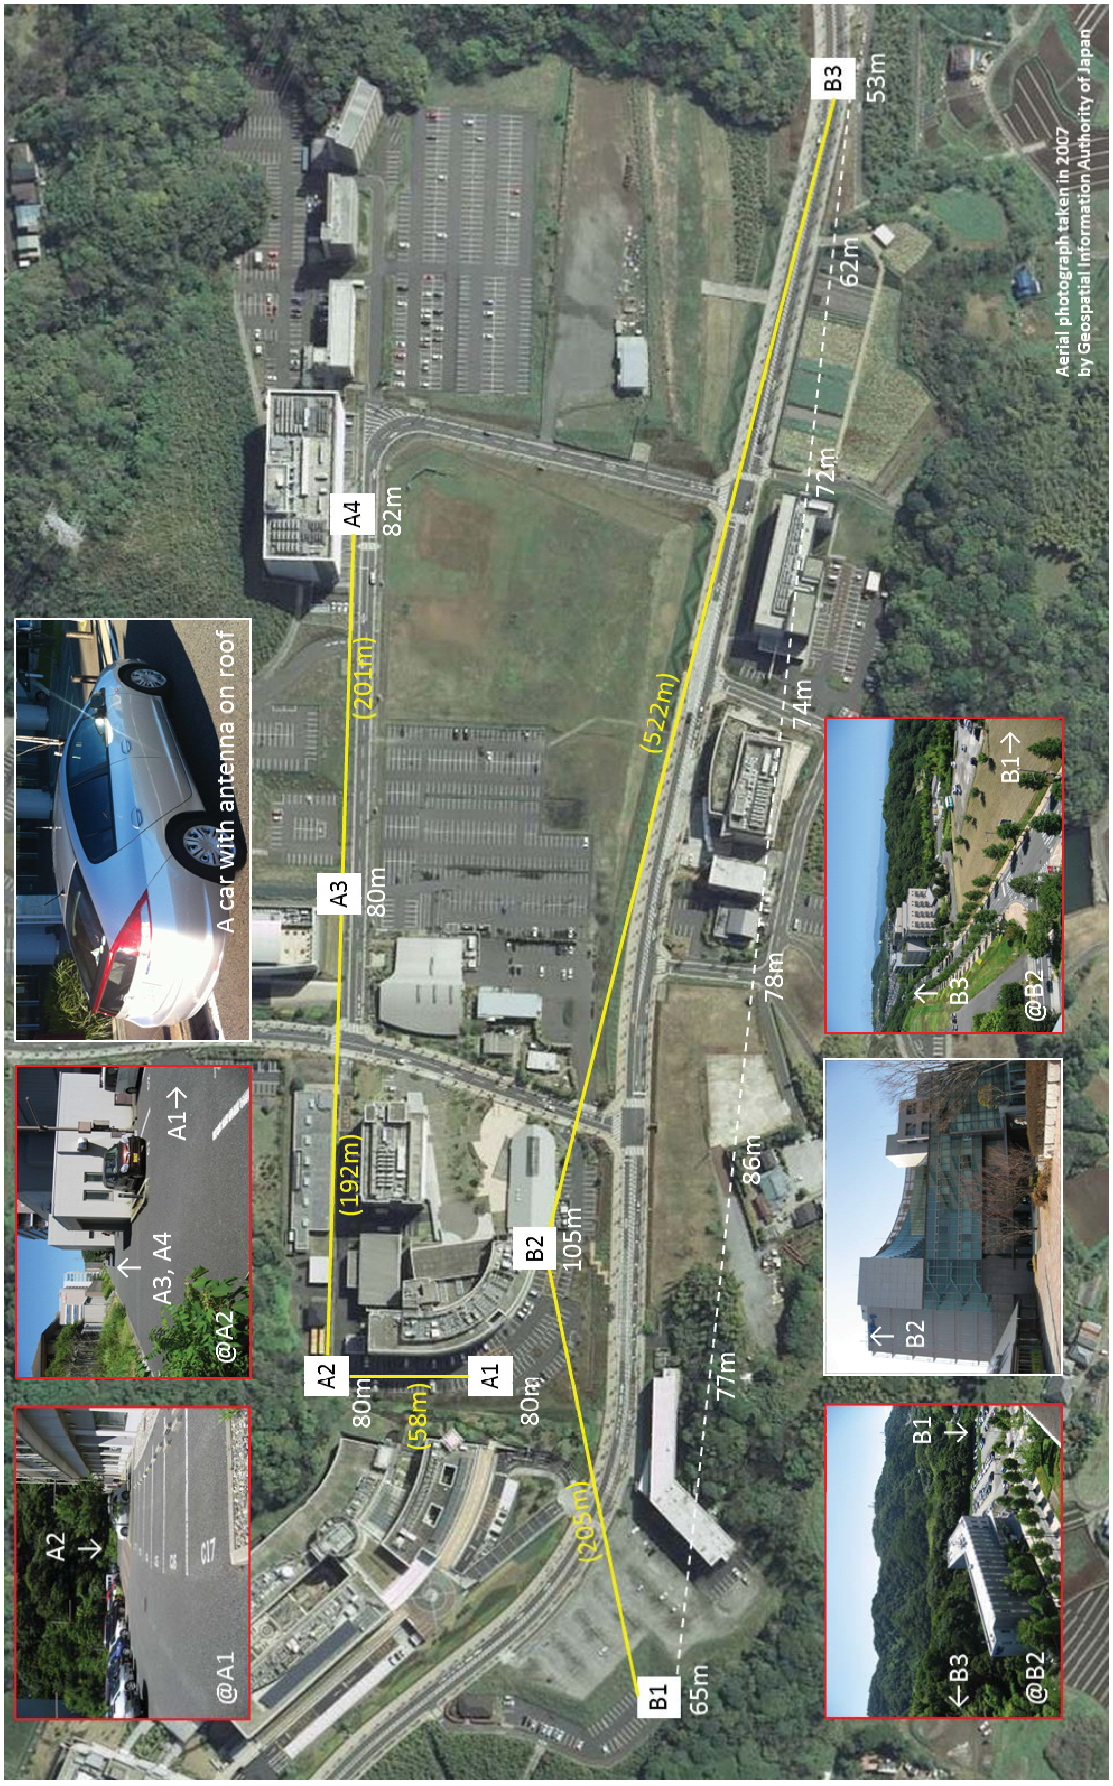

Fig. 5. Location and altitude of deployed nodes for the field experiments
(Lines in yellow are links between nodes. Numbers in yellow on the lines are the distance between the nodes.
Numbers in white are altitudes above the sea at each location. Photos in red frames are taken from the locations of noted nodes.)

1) Scenario 1 (A1-A2-A3)

The throughputs in the links A1-A2 and A2-A3 were all between 900 and 1300 kbps as in Table II (a). Throughput of the multi-hop path A1-A2-A3 are around one third of the single link throughput. This trend is the same as the laboratory environment test described in section IV.

2) Scenario 2 (A2-A3-A4)

The throughput was between 906 and 1090 kbps in link A2-A3 and between 152 and 277 kbps in link A3-A4. The reason for the lower throughput in link A3-A4 could be lower RSSI at these nodes or some spot noise around A4. Throughput of the multi-hop path A2-A3-A4 was between 136 and 226 kbps. It is observed that the multi-hop throughput was slightly lower than the lower single link throughput (A3-A4) in each traffic direction.

Compared with scenario 1, the large throughput deterioration by around one third of single link throughput was not observed. Rather, bottleneck in this scenario was in the link with lower throughput.

3) Scenario 3 (B1-B2-B3)

In link B1-B2, the throughput was 1240 kbps from B2 to B1, but around one fifth of it from B1 to B2. Note that B2 was the building roof top and B1 was lower parking area, which had 40m altitude gap over 205m horizontal distance as seen in the lower photos taken at B2 in Fig. 5. Because TV signals in other channels are stronger at B2 since the altitude is higher, the RF circuit of the device at B2 could be affected by the high power signal input in the TV band as the device has only wide band front-end filter covering just entire TV band.

In link B2-B3, the throughput was 235 kbps in both directions. Distance between B2 and B3 is 522 m and RSSI was -88 to -86 dBm that were close to the sensitivity level as in Section IV. This is the reason for lower throughput.

The multi-hop (B1-B2-B3) throughput was 95 kbps in transmission from B1 to B3 and 168 kbps in transmission from B3 to B1. From B1 to B3, throughput of the two single links were similar and the multi-hop throughput was close to one third of them, which was the same trend as scenario 1. On the other hand, multi-hop throughput from B3 to B1 was capped by the lower single link throughput (B2-B3) as in scenario 2, though the former was 70% of the latter. As seen in altitudes on the dotted line in Fig. 5, there is a quite high hill in between B1 and B3, therefore their direct link is very difficult.

4) Discussion

Our previous experiments [8] show that IEEE 802.11af system can establish a link over 3.7 km in metropolitan area with TX power of 36 dBm EIRP which is current typical regulations in the world [1-3]. Therefore, it is possible to extend length of each link of the proposed system once the TX power is increased. This means that communications over 10 km to 20 km can be achieved with 4 or 5 nodes using only one TV channel.

From the results in scenario 3, it is said that communication area of other nodes becomes extensively large like cellular networks when one of relaying node is put at high altitude. This idea can help for temporary wireless network deployment, for example, in disaster recovery activities.

The number of nodes in the experiments were just three in this paper. But, as the number of nodes increases, the spectrum utilization efficiency could increase compared with the approach to assign different channels to different links because the ratio of active links without traffic increases. Also, utilization of directional antennas can extended each single link, eliminate interference from TV signals in the same and other channels, and manage coexistence with other TVWS systems. These topics are left for future studies.

VI. CONCLUSIONS

In this paper, broadband mesh network was proposed based on IEEE 802.11af by extending to ad-hoc mode. Prototype system was developed and field experiments were conducted in three practical scenarios. Measurement showed that two hop network realizes up to one third of single hop throughput. The experiment proofed that the system can be operated in limited one TV channel. As there are large demands for long-distance wireless backhaul network operating in TVWS such as in rural area and islands, introduction of the mesh networking to broadband TVWS communications is a big progress. As future works, experiments in a large area with some practical applications are planned. Issues specific to TVWS such as difference of allowed TX power and collaboration with White Space Database need to be studied.

***Abstract*—3D location knowledge of sensor node in a sensor network has many practical applications. This paper proposes a new algorithm for finding 3D location of sensor node in a sensor network by using radiation pattern of antenna with Received Signal Strength Indication (RSSI). Proposed localization algorithm is developed by considering target node equipped with half wave dipole antenna which has omnidirectional radiation pattern. The results show that proposed algorithm estimates 3D location of sensor node in a sensor network with low average error ($< 0.5m$), when compared to its actual location.**

***Index Terms*—Radiation pattern, RSSI, 3D localization.**

I. Introduction

Recent advances in micro-electromechanical systems, wireless communication technologies and digital electronics have brought us closer to the vision of pervasive Wireless Sensor Networks (WSN). Development in WSN enhanced smartness in controlling and monitoring sensors in a sensor network [1]. WSN have a number of potential applications such as sensing environment physical factors like temperature, humidity and also for monitoring and detecting chemicals, smokes etc. In most of application areas such as military, habitat sensing, target tracking, forest fire location detection and marine monitoring, knowledge of every sensor node location is very crucial to understand application context.

Authors of [2] discussed three basic advantages of having the sensor nodes location information. Firstly, location information is required to estimate the location of an event of interest for example intruder location. To deploy relief and rescue in a battlefield the location of enemy tanks is crucial. Secondly, knowledge of location information facilitates a number of application services, such as helping doctors by providing the location of nearby medical facilities in a smart hospital. Third, location information find its applications in geographical routing ([3] and [4]), network coverage checking [5] and location-based information querying [6].

For outdoor localization applications GPS is used, but in indoor environment GPS is inaccurate because of poor signal strength. Most of existing localization techniques are 2D localization techniques. In [7] and [8] RSSI based localization algorithms for 2D are discussed. In real world applications sensor nodes are deployed in 3D. To estimate 3D location of sensor node we need to develop 3D localization algorithm.

Existing localization techniques are broadly divided into two types. First one is range-based localization techniques and second one is range-free localization techniques. Range-based localization techniques are dependent on range measurement techniques (distance measurement, angle-of-arrival measurement techniques) for localization. The localization techniques which depends on RSSI and path loss modelling of environment ([9]) falls under category of range-based localization. The range-free localization techniques do not use range measurement techniques. They use topology, connectivity information for localization. Authors of [10] discuss basic centroid localization algorithm which falls under category of range-free localization algorithms.

Most of the 2D and 3D localization techniques which depend on RSSI and path loss model always consider antenna radiation pattern as isotropic i.e. antenna radiates uniform power in all directions [11]. In practice isotropic antenna does not exist. Omnidirectional antenna is used as isotropic antenna because it radiates uniform power in all azimuth directions, but it has a deep null in the orthogonal elevation direction. It radiates less power in axial direction of the antenna as shown in Fig. 1. Due to this, omnidirectional antenna or half wave dipole antenna radiation pattern gives less received power at nodes which are placed at the bottom of the antenna. In practical scenario because of the antenna radiation pattern effect localization error could increase. This motivated us to propose new radiation pattern based 3D localization algorithm, which considers radiation effect to give less error in localization.

A. Related works

In [12] authors proposed a novel centroid algorithm for 3D. Authors of [13] proposed new 3D DV-Hop Localization algorithm which is extended version traditional range-free DV-Hop algorithm in to 3D. In [14] authors described a range-free 3D azimuthally defined area localization algorithm. Authors of [15] proposed unitary matrix pencil algorithm for range-based 3D localization. It depends on time-of-arrival (TOA) estimation of ultra wideband signal using unitary matrix pencil algorithm. Paper [16] proposed a 3D positioning algorithm based on RSSI, which uses maximum likelihood estimator to estimate 3D location. Authors of [17] and [18] proposed

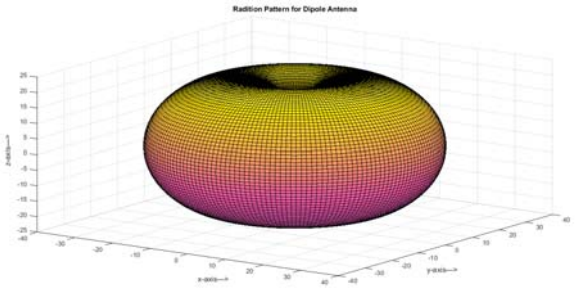

Fig. 1: 3D radiation pattern of half wave dipole antenna.

directional antenna based 2D localization techniques. These techniques depend on radiation pattern of the antenna.

In this paper we propose antenna radiation pattern based 3D localization technique by using node's omnidirectional antenna radiation pattern.

The rest of the paper is organized as follows. Section II describes proposed 3D localization algorithm. Section III describes the algorithm implementation and simulation setup for 3D localization. Section IV describes simulation results analysis. Finally, section V concludes the paper with future scope of work.

II. Proposed 3D localization algorithm

This section describes the proposed radiation pattern based 3D localization technique. We assumed that target node (the sensor node which location has to be estimated) is equipped with half wave dipole antenna, which has omnidirectional radiation pattern. In all directions, omnidirectional antenna radiation pattern is not same. It radiates less power in the axial direction of antenna. 3D radiation pattern of half wave dipole antenna is shown in Fig. 1.

A. Estimating 2D location of target node

We considered that target node is placed above the XY-plane with antenna in Z-axis direction. Omnidirectional antenna radiates power concentrically in horizontal direction with circular patterns as shown in Fig. 2. Received power from transmitting antenna at equidistant beacon locations is almost same on 2D plane (ground plane). The 2D location of the target node can be estimated by locating center of the circular patterns. To find out center of the circular patterns on 2D plane where beacon nodes are placed, the plane is divided in to circular patterns which are having arbitrary center point. These circular patterns form rings on 2D plane. Variance of received powers is computed over each ring. The mean of variances of received power where it goes to minimum, that center point of circles is regarded as 2D location of the target node.

To estimate target node 2D location (X_e, Y_e), we considered n beacon nodes in 2D plane. Location of beacon nodes are (x_i, y_i) where $i = 1, \ldots, n$ (a sensor node which is placed on mobile robot can be used as beacon node to get n beacon node locations [11]). Received power of i^{th} beacon node is Pr_i. Rn_{kl} represents l^{th} ring centered at an arbitrary point

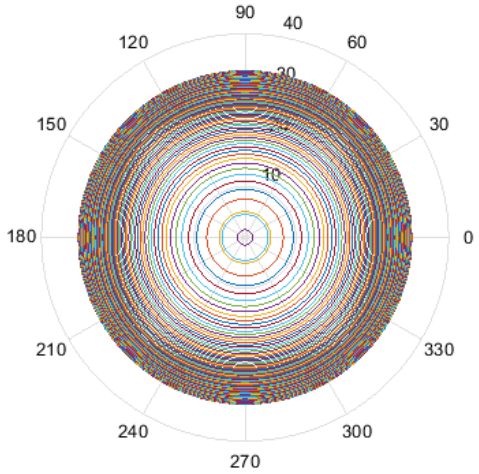

Fig. 2: Power distribution of the omnidirectional antenna in horizontal plane.

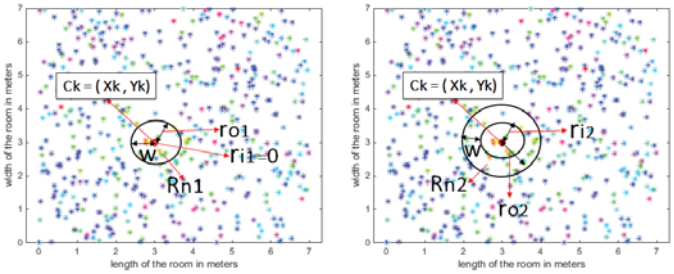

Fig. 3: The defined area is divided in circular rings.

$C_k = (x_k, y_k)$, where the radius of inner circle is ri_l, outer circle is ro_l and the width of each ring is w. Consider D_{ki} is the Euclidean distance between each points on 2D plane (x_i, y_i) and an arbitrary point $C_k = (x_k, y_k)$ which is calculated from equation (1). d_{1l} is the minimum distance between l^{th} ring's inner circle circumference and the points lying inside the ring. d_{2l} is minimum distance between l^{th} ring's outer circle circumference and points lying outside the ring i.e. points which distance $D_{ki} > ro_l$. Pt_i is the set of points of beacon node locations. Algorithm starts at an arbitrary point C_k with $ri_l = 0$ and $ro_l = w$. In next step if $d_{1l} < d_{2l}$ then $ri_l = d_{1l}$, $ro_l = ri_l + w$ else $ro_l = d_{2l}$, $ri_l = ro_l - w$. Fig. 3 shows plot of two iterations. In iterative process d_{2l}, d_{1l}, ri_l, ro_l will be update until $A_{kl} = \{\emptyset\}$.

$$D_{ki} = \sqrt{(x_i - x_k)^2 + (y_i - y_k)^2} \tag{1}$$

Here the set of points located in the ring Rn_{kl} are represented by $A_{kl} = \{Pt_i \mid Pt_i \in Rn_{kl}\}$. E_{kl} represents the mean of received power at different beacon nodes in the ring Rn_{kl} and calculated by equation (2).

$$E_{kl} = \frac{\sum_{Pt_i \in A_{kl}} Pr_i}{n_{kl}} \tag{2}$$

n_{kl} is the number of point of the set A_{kl}. Variance of received power values of each ring V_{kl} calculated using equation (3).

$$V_{kl} = \frac{\sum_{Pt_i \in A_{kl}} (Pr_i - E_{kl})^2}{n_{kl}} \tag{3}$$

$$EV_k = \frac{\sum_l (V_{kl})}{M_k} \tag{4}$$

Equation (4) is used to find the mean of the variances of the rings centered at C_k. Here M_k is the total number of rings for C_k. Finally the estimated position (X_e, Y_e) is determined using the following equation (5).

$$(X_e, Y_e) = C_k \text{ which minimizes } EV_k \tag{5}$$

B. Estimating height of the target node

The gain of omnidirectional antenna in vertical direction is lower than horizontal direction [19] as shown in Fig. 1. Thus, received power measured at the beacon nodes under the target node will be low. The average value of received power at beacon nodes from target node will decrease as target node height increases. This fact helped us to propose a new relative height estimation method for 3D localization.

To calculate average received power of beacon nodes under target node, a circle with radius r from estimated 2D location of the target node (X_e, Y_e) is considered. Set of Beacon positions M, which distance from (X_e, Y_e) is less than r is considered, i.e. $M = \{Pt_i \mid D_{ki} < r\}$. N_M is the number of beacon node in the set M. Average received power of beacon nodes P_{avg} is calculated using equation (6).

$$P_{avg} = \frac{\sum_{Pt_i \in M} Pr_i}{N_M} \tag{6}$$

Specifically, the proposed algorithm estimates the relative height Z_{ej} of target nodes N_j. Here we assumed that all target nodes heights are uniformly distributed along Z-axis with different 2D locations. First we find the average received power of all target nodes (inside the circle with radius r under target nodes). The minimum P_{avg} value is denoted by $P_{avg_{min}}$, the corresponding height of $P_{avg_{min}}$ is H_{max}. To estimate relative height of other target nodes, received average powers of all target nodes are divided in to groups. K-means clustering algorithm is used for grouping the received average powers of different target nodes with different heights. K-means algorithm will give group numbers according to received average powers. All the target nodes are classified into M groups from G_1 to G_M depending on its P_{avg}. The height of a target node in group G_h (where group number $h = 1, 2, ..., M$) is estimated by following equation (7).

$$Z_{ej} = \frac{H_{max}}{M} * h \tag{7}$$

III. Algorithm implementation and simulation setup for 3D localization

The proposed algorithm is implemented using Matlab software. Radiation pattern of the half wave dipole antenna is generated with reference of [21], [22] using Matlab. To implement the algorithm we considered beacon nodes are randomly deployed on 2D plane. Target node is considered above 2D plane (which is placed in 3D location). Received power Pr_i at randomly deployed beacon nodes (x_i, y_i) depend on gain of the antenna at respective positions. Antenna Transmit gain $G_t(\theta, \phi)$ and antenna receive gain $G_r(\theta, \phi)$ are function of azimuth angle ϕ and elevation angle θ. Transmit and receive antenna gain of beacon nodes will be different for different azimuth angle ϕ and elevation angle θ with respect to target node. Depending on these azimuth and elevation angles, antenna gains are mapped to different beacon node's location. To find received power at beacon node's location Revised Hata Okumara path loss model [20] is used (8).

$$\begin{aligned} logD_i = \frac{1}{10\eta}[P_t - Pr_i + G_t(\theta, \phi) + G_r(\theta, \phi) \\ - X_\alpha + 20log\lambda - 20log(4\pi)] \end{aligned} \tag{8}$$

Where $D_i \rightarrow$ distance between the target node to all beacon nodes (X_t, Y_t, Z_t) and i^{th} Beacon node (x_i, y_i).

$G_t(\theta, \phi)(dBi) \rightarrow$ Transmit antenna gain

$G_r(\theta, \phi)(dBi) \rightarrow$ Receiver antenna gain

$P_t(dBm) \rightarrow$Target node transmit power

$Pr_i(dBm) \rightarrow$ Measured received power at i^{th} beacon position

$\eta \rightarrow$ Measure of influence of obstacle like partitions and obstacles in indoor environment ranges from 4 to 5 and for free space it is equal to 2.

$X_\alpha \rightarrow$ Normal random variable with standard deviation of α and varies from 3dB to 20dB.

TABLE I: Path loss model parameter values used for simulation

Parameter	Value
P_t	-3 (dBm)
X_α	3 (dB)
λ	0.125 (meters)
η	2.5

A. Simulation setup

For simulation purpose we considered area of 7m*7m, number of beacon nodes are 1000 which are placed at random locations. All beacon nodes are placed on 2D plane with

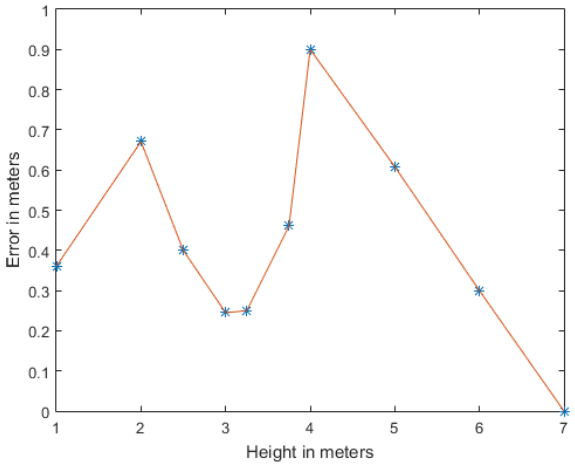

Fig. 4: Predicted location error vs height of the target nodes

random azimuth angle. We considered all target nodes and beacon nodes are equipped with half wave dipole antenna. Along with this setup 10 target nodes are considered which are placed at different 3D locations. Considered number of groups are $M = 10$ and considered maximum height is $Hmax = 7m$ which is maximum height of the considered target nodes. To calculate average received power of beacon nodes under the target node, a circle with radius $r = 0.5m$ which centered at estimated 2D location is considered. TABLE I shows path loss model parameters considered for simulation.

IV. Simulation Results analysis

Estimated location error with different heights is plotted in Fig. 4. Actual, estimated locations are tabulated in TABLE II.

TABLE II: Estimated and actual location of the sensor node at different heights

Actual locations (m)			Estimated locations (m)		
Xt	Yt	Zt	Xe	Ye	Ze
0	0	1	0.2	0	0.7
1	2	2	1	1.7	1.4
2	3	2.5	2	3	2.1
4	1	3	4.1	0.9	2.8
3	3	3.25	3	3	3.5
5	2	3.75	5.1	2	4.2
6	6	4	6	6	4.9
3.5	1.5	5	3.5	1.6	5.6
4	2	6	4	2	6.3
2	4	7	2	4	7

The error of the estimated 3D location of the target node to actual location of the target node is calculated by using equation (9).

$$E_{rr} = \sqrt{(X_t - X_e)^2 + (Y_t - Y_e)^2 + (Z_t - Z_e)^2} \quad (9)$$

Where $(X_t, Y_t, Z_t) \rightarrow$target node real location.

$(X_e, Y_e, Z_e) \rightarrow$ target node estimated location.

Estimated average error for 10 different locations with 10 different heights given in TABLE II is $0.4196m$. This result is more accurate compared to existing algorithms [11].

V. Conclusion

In this paper we proposed an antenna radiation pattern based 3D localization algorithm for estimating the 3D location of sensor node in a sensor network. The simulation results shows that the proposed algorithm gives less average error ($< 0.5m$) in estimating 3D location of target node compared to it's actual location. Our future plan is to implement proposed algorithm in real environment and test with different experimental setups.

Abstract—After the great east Japan earthquake, a mission of location and short message communication was added to Japanese Quasi-Zenith Satellite System (QZSS). This paper describes a novel Spread Spectrum CDMA (SS-CDMA) satellite communication system for this mission. By using long spread code, both long distance communication (high processing gain) and large capacity can be obtained. Due to the existence of long Round Trip Time (RTT) of satellite communication, a complex and real time access control method of cellular phones can't be adopted. Therefore, a novel frame slotted ALOHA with flag method and no transmit power control schemes has been proposed. The proposed access control method does not requires real time feedback or response and is applicable to huge capacity of several millions users. The design result shows the feasibility of location and short message communication system which can handle 3 million users within an hour using 2.68 MHz bandwidth.

Keywords—Satellite Communication, QZSS, CDMA, Spread Spectrum, GPS, Microwaves, Resilient Wireless Network

I. INTRODUCTION

In the event of large scale disaster, terrestrial communication infrastructure is heavily damaged. To reduce the risk of disaster, emergency/relief communication becomes important, but no wired/wireless backbone network will be left to connect the damaged area to the outside. Satellite communication has been recognized as the citadel of emergency/relief communication network [1].

After the great east Japan Earthquake, Japanese government decided to add the new mission of "location and short message service for evacuees" to QZSS (Japanese positioning system) [2]. By using this system, the data (short message of the evacuees' situation and their positioning data) can be transmitted from their mobile terminal with less than 1W RF power. This system's capacity should be more than 1,000,000 users/hour. To satisfy this requirement, we propose the SS-CDMA short message/location system [3]. By using CDMA system using long spread codes, both large capacity and long communication distance of 39,000km can be achieved. Since the round trip time (RTT) of 0.52 sec. exists, power control system with real time feedback from the base station used in the CDMA cellular systems can not be employed. We propose a novel CDMA system with no Tx power control [3],[4]. In order to realize the synchronization of the chip using positioning data and delivered GPS clock (CLK) [5]. We also propose the novel access control scheme based on frame slotted ALOHA [6]. By combining new technologies, the requirements for "location and short message service for evacuees" can be satisfied.

II. SYSTEM IMAGE AND LINK BUDGET DESIGN [3]

Figure 1 shows the system image of QZSS short message communication using SS-CDMA scheme. The satellite communication system has less near-far resistant than cellular system, because the relatively long/equal communication distance between the terminals on the earth and the satellite. By using non-directive or hemisphere beam antenna for the terminals and by transmitting same RF output power, the receiving power level from each terminal becomes almost same level. Therefore, power control which is widely used in CDMA cellular phone system is not necessary. Fig.2 shows the link budget design of proposed QZSS system. Long SS code enables both long communication distance of 39,000km and high CDMA capacity of 10,000 users. Fig,3 shows the packet structure and Table 1 shows the initial design result of QZSS short message communication in ideal case.

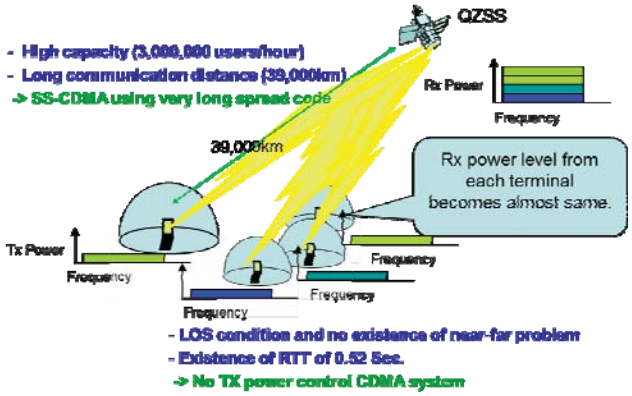

Fig.1 System image of QZSS short message communication using SS-CDMA.

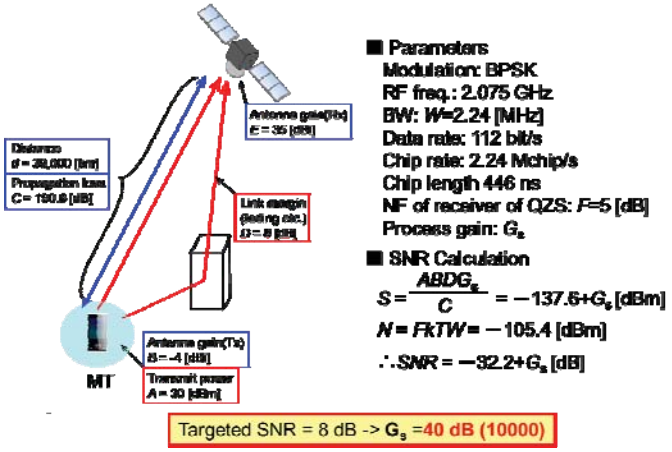

Fig.2 Link budget design of proposed QZSS system.

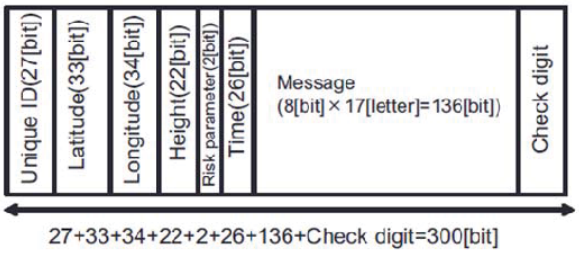

Fig.3 Packet structure.

Table 1 Initial design of QZSS short message communication in ideal case.

Process gain	dB/IR
Ideal multiplexing number	10,000
Data rate	112 bps
Packet size	300 bit
Tx time for 1 packet (1 user)	2.67 Sec.
Ideal capacity per hour	13,500,000 Users/hour

III. Code Design and Synchronization of SS-CDMA [4]-[5]

SS-CDMA communication system realizes the direct access from terminals to a satellite and accommodates several million users using long spreading codes. We design the channel which realizes the direct access from terminals to the satellite and evaluate influence of orthogonality breaking in high density CDMA using long spreading code. In the proposed system, the multiplexing rate should be set to extremely high value to accommodate several millions terminals, Therefore, keeping orthogonality among all users is very important. We selected orthogonal M-sequence for this high capacity SS-CDMA usage. "0" is added to the sequence which is obtained by cyclic shifting 1chip of M-sequence code. In the case of zero phase difference, cross correlation becomes zero. Since the single M-sequence is essentially used, any N-1 sequences can be prepared from N length code. This method is suitable to very large number multiplexing

We calculate the required accuracy of timing jitter and frequency offset by computer simulation. The simulation conditions are shown in Table 2. Due to the limitation of computer capacity for simulation, we scale down the capacity to 1/10 size. The simulated BER vs. timing accuracy is shown in Fig.4. The simulated BER vs. frequency accuracy is shown in Fig.5. The simulated results show the time accuracy is 56 ns (1/8 chip) and frequency accuracy is 0.01 ppm are required in to realize the accommodation rate of 100 % within 1dB Eb/No/Gs degradation.

Table 1 Simulation conditions (*:1/10 scaling for simulation)

Modulation scheme	BPSK
Coding	Convolutional Code (R=1/2)
Bandwidth	224 kHz *
Chip rate	224 kchip/s *
Symbol rate	220 symbol/s
Spreading code	Orthogonal M sequence
Spreading factor	1024 *
Transmit & Receiver filter	Root raised cosine filter (α=0.5)
Channel model	Adaptive white Gaussian noise

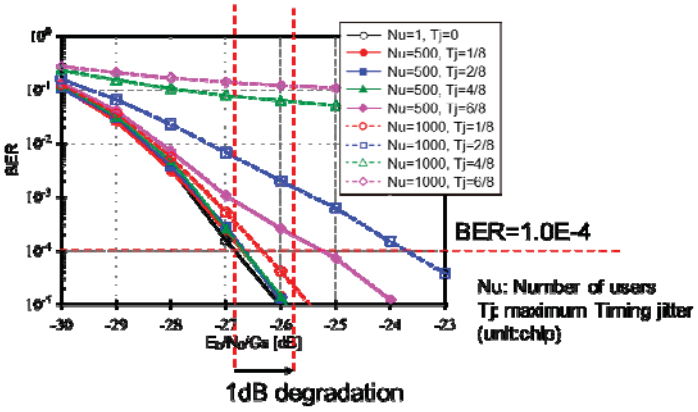

Fig.4 Calculated requirement of timing accuracy.

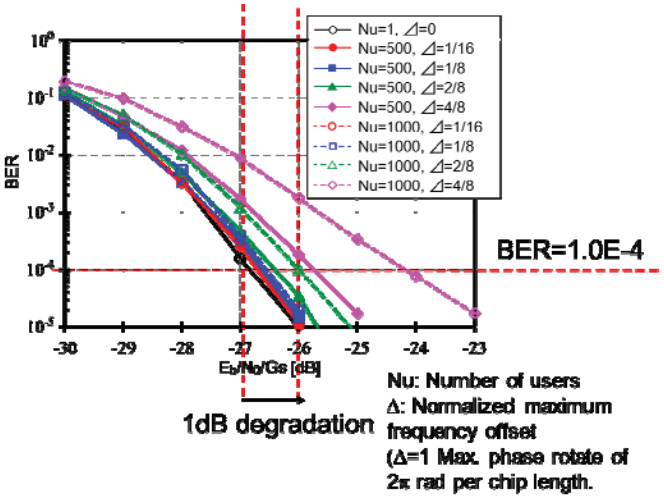

Fig. 5 Calculated requirement of frequency accuracy.

Figure 6 shows the proposed block diagram of QZSS short message communication terminals. These time and frequency accuracies can be achieved by using a high accurate positioning data and precise clock delivered from the QZSS as shown in Fig.7. We have measured the actual time and frequency accuracies by GPS locked TCXO (Furuno, GF-180TC) which can be used in the mobile terminals. The photo of measured GPS locked TCXO module is shown in Fig.6. An example of measured 1PPS Clock timing variation is shown in Fig.8. In this case, the timing error is less than 10ns. The measured time (1PPS clock) error for CDF of 99% is less than 20ns as shown in Fig. 9 and is smaller than the requirement. Frequency accuracy is also verified by the measurement.

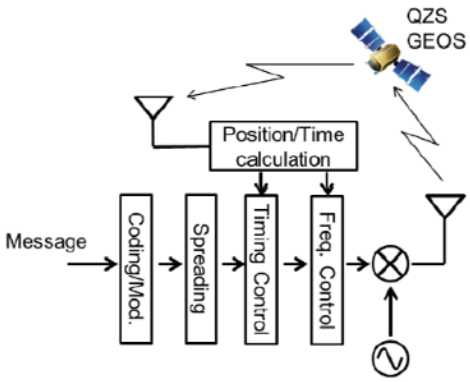

Fig.6 Block diagram of QZSS short message communication terminals.

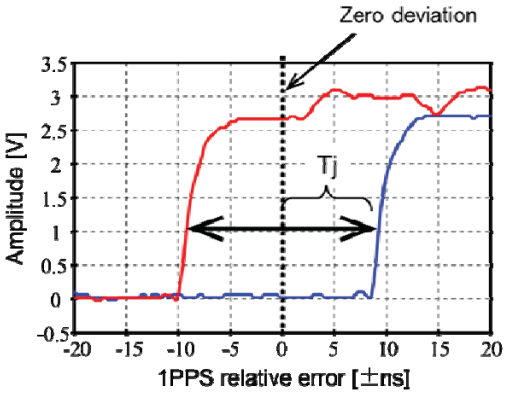

Fig. 8 Example of measured 1PPS clock timing variation.

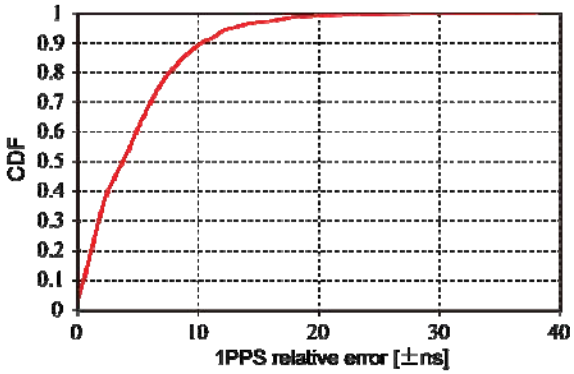

Fig.9 Measured timing error of GPS locked TCXO.

IV. Large Capacity / High Efficiency Access Control Scheme Using Flag Signal [6]

In the case of satellite communication system such as the proposed QZSS short message system, due to the existence of round trip time (RTT) and the relatively narrow control link band width, it is hard to use the access control scheme that we use for terrestrial wireless communication such as cellular phone. We propose novel/simple access control scheme which

attains high channel efficiency/capacity. In this system, all mobile terminals send flag signals compounded from multiple symbols at the same time. The approximate number of mobile terminals can be monitored by the received total power level of the added symbol, and resource can be assigned. The estimated accuracy of the number of mobile terminal is evaluated by theoretical analysis and numerical simulation. Fig.10 to Fig.12 show the proposed slotted ALOHA with flag method access control scheme. By using flag method, we can estimate the number of senders and can prepare the suitable length of frame. Fig.13 explains the concept and basic operation of proposed reservation channel (R-ch) method [6]. By adding this R-ch to the slotted ALOHA with flag method, both high capacity and high efficiency access control can be realized even in the case of very narrow control channel with RTT of 0.52s.

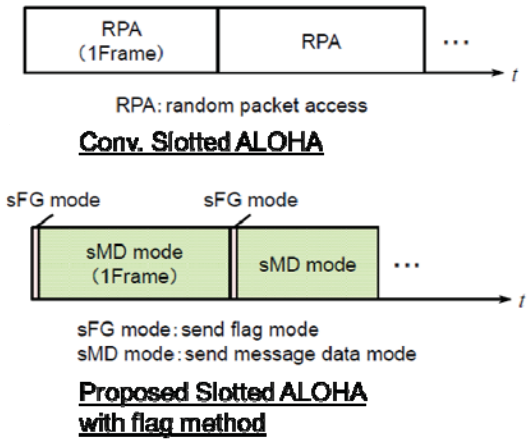

Fig.10 Proposed slotted ALOHA with flag method.

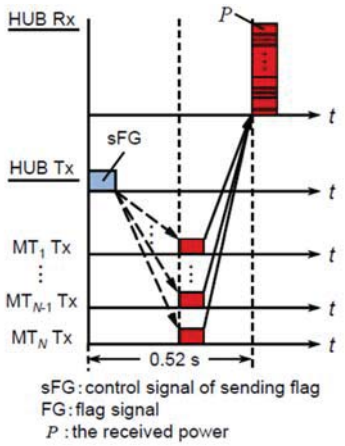

Fig. 11 Basis of proposed flag method in the sFG to estimate the number of senders. The number can be estimated from the received power level of total flag signal (P).

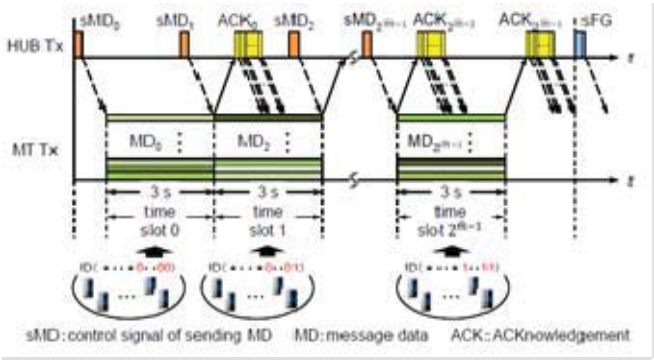

Fig. 12 Basis of proposed access control scheme using flag method.

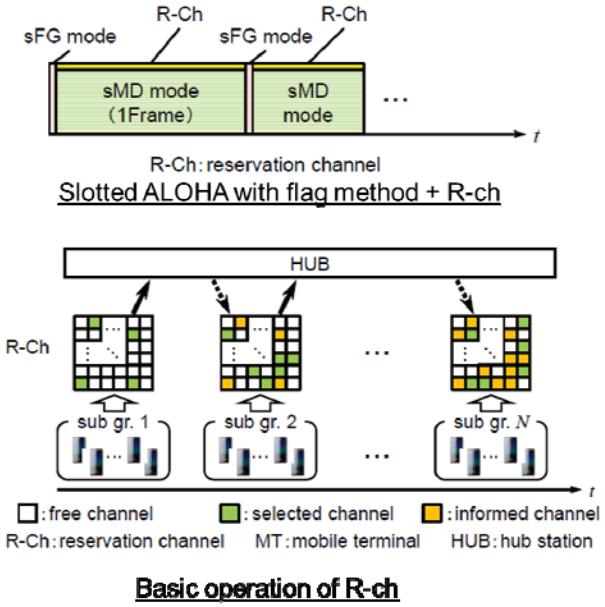

Fig.13 Concept and basic operation of proposed reservation channel (R-ch) method

Fig.14 shows the simulated results. By using proposed slotted ALOHA with flag method, 3 million users can complete their communication within an hour (3,600 sec.) By adding R-ch control scheme, time to complete will be reduced to ½. The results show that 3 million users' short message can be accommodated in an hour.

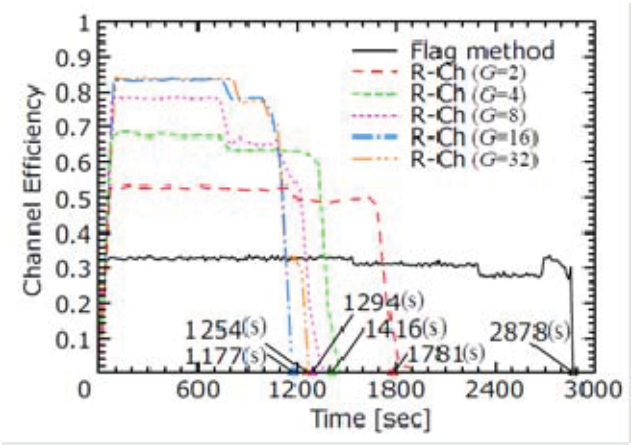

Fig.14 Time to complete 3 million users' communication .

V. Conclusion

After the great east Japan earthquake, a mission of location and short message communication was added to QZSS. For this mission, we propose a novel SS-CDMA satellite communication system for QZSS disaster relief short message communication for evacuees.

(1) Long spread code is used to obtain both long distance communication and large capacity .

(2) Due to the long Round Trip Time (RTT), a complex and real time access control method of cellular phones can't be adopted. Therefore, simple access control method is proposed.

We confirm our proposals by simulations and/or measurements.

***Abstract*—In cellular optimization, the UL and DL the values from carrier-to-noise-plus-interference ratio (CNIR) from/at the mobile station are very important parameters. From a detailed analysis of its variation with the coverage and reuse distances for different values of the Channel Quality Indicator (CQI) and given ITU-R propagation models, an evaluation of the possible range for the reuse factor, r_{cc}, of LTE-A is performed for the DL. By considering CQI and reference CNIR requirements recommended by 3GPP, DL peak bit rates along with the Transport Block Size assumed for single stream and bandwidths of 10 and 20 MHz, PHY and supported throughputs are analysed. HetNets with Carrier Aggregation (CA) are considered, where macro cells operating at 800 MHz provide coverage and small cells (SCs) operating at 2.6 GHz provide throughput enhancement at hotspots. A clear decrease of the supported throughput for the highest coverage distances in NLoS propagation conditions is shown. Besides, owing to existence of a breakpoint distance, d_{BP}, in the two slope model for LoS propagation, with SCs, a maximum occurs for system capacity for coverage distances, R, in the range between d_{BP}/r_{cc} and d_{BP}.**

Keywords—LTE-Advanced; CNIR; ITU-R propagation model; radio and network optimization; system capacity; HetNet

I. INTRODUCTION

In nowadays wireless cellular networks, not only mobile services and applications usage is increasing each year, leading to an expansion of mobile data traffic, but the pace at which it is growing is accelerating. According to [1], in 2013 mobile data traffic was nearly 18 times the size of the entire global Internet in 2000. One Exabyte of traffic traversed the global Internet in 2000, and in 2013 mobile networks carried nearly 18 Exabyte's of traffic. In 2013 alone, 526 million mobile devices and connections were added, the global mobile data traffic grew 81 % and mobile video represented 53 % of all mobile traffic and by 2018 it will reach 69 %. Moreover, mobile-connected devices exceed the world's population by 2014. Monthly mobile data traffic will reach 15.9 Exabyte's by 2018 and between 2013 and 2018 the annual growth rate is 61 %, i.e., mobile data traffic will increase nearly 11-fold between 2013 and 2018. These statistics show beyond the shadow of a doubt that wireless and cellular networks technologies need to be enhanced to support such demands. As such, this paper gives contributions to the basic limits of the optimization and planning of 4G cellular networks in a context of heterogeneous (HetNets) Long Term Evolution - Advanced (LTE-A) and spectrum management. LTE-A provides seamless Internet Protocol (IP) connectivity between user equipment (UE) and the packet data network (PDN), and an air interface based on Orthogonal Frequency Division Multiplexing (OFDM) in the downlink (DL) and single-carrier frequency-division multiple access (SC-FDMA) in the uplink (UL), both providing high flexibility in the frequency-domain scheduling. LTE-A has the flexibility to support time-/frequency-division duplexing (TDD/FDD) and half-duplex FDD schemes.

The main goal of cellular coverage is to offer access to mobile users in a cell, while guaranteeing quality of the received signal in both DL and UL directions, even for the users at the cell edge. As resources, e.g., radio frequency channels, need to be reused in different geographical zones (but not in the closest proximity), the impact of interference among co-channel cells needs to be evaluated in both DL e UL directions. Furthermore, this interference is heavier in users at cell edge, who may suffer from low connection quality. Therefore, a comprehensive study on the variation of the UL/DL carrier-to-noise-plus-interference ratio (CNIR) from/at the Mobile Station (MS) with different system parameters is critical in the context of LTE-A optimization. In this work, we are just considering DL. The variation of CNIR with the coverage and reuse distances is analysed for different values of the Channel Quality Indicator (CQI) and respective Modulation and Coding Scheme (MCS), considering the macro and pico cellular layers from a HetNet.

OFDM is a digital multi-carrier modulation scheme that extends the concept of single subcarrier modulation by using multiple subcarriers within the same single channel. Rather than transmit a high-rate stream of data with a single subcarrier, OFDM makes use of a large number of closely spaced orthogonal subcarriers that are transmitted in parallel. Each subcarrier is modulated with a conventional digital modulation scheme (such as QPSK, 16QAM, 64QAM.) at low symbol rate.

The goal of considering adaptive modulation is to choose the appropriate MCS for transmission in each carrier, given the local CNIR [2]. The MCS is chosen from an LTE-specific look-up table according to the provided Channel Quality Indicator (CQI) feedback [3]. The corresponding MCS value should achieve the maximum possible throughput by guaranteeing that the Block Error Ratio (BLER) is a bellow a given threshold.

Table I shows the mapping established with the MCS index and reference CNIR requirements recommended by 3GPP for DL, Los/NLoS as well as the spectral efficiency, S_{eff}. Table II presents DL peak bit rates, R_p, considered for single stream and bandwidth of 10 and 20 MHz.

TABLE I. MINIMUM CNIR, MODULATION AND SPECTRAL EFFICIENCY VERSUS MCS, FOR LTE, AND VALUES FOR THE VERTICAL ASYMPTOTE FOR DL

Macro/Pico	0.8 / 2.6	16 / -7	17	0	10 / 20	5

The remainder of the paper is organized as follows. Section II addresses the interference, noise and frequency reuse trade-offs involved in LTE radio and HetNet optimization considering different MCSs, LoS versus NLoS propagation, comparing the behaviour of the 800 MHz and 2.6 GHz frequency bands (pico/ macro cellular layers, respectively) whilst briefly mentioning the analytical formulations. Section III presents a detailed analysis of LTE system capacity considering assumptions for different levels of MCSs, and discusses original results for the equivalent supported throughput as a function of the coverage distance. Finally, conclusions are drawn in Section IV.

II. CELLULAR RADIO AND HETNET OPTIMIZATION

In HetNets, cellular radio/network optimization must consider interference in obtaining the maximum coverage distance since it is a critical limitation in cellular systems dimensioning process. Noise is also an essential factor for the interference analysis, since it is always present in communications. Therefore, cellular optimization has to simultaneously consider carrier-to-noise and carrier-to-interference constraints. This work evaluates a 3GPP Carrier Aggregation (CA) scenario [4]. This scenario allows a flexible use of fragmented spectrum in different frequency bands. A lower frequency, 800 MHz, at the macro base station (eNB) layer provides coverage while the 2.6 GHz frequency band, at a pico-cell layer, improves throughput at hot spots. Mobility through CA is performed based on the macro eNB. The work considers LoS and NLoS propagation. Given the future reality in Portugal and Europe, the values for the evaluated bandwidth, BW, are 10 and 20 MHz both for the 800 MHz and 2.6 GHz frequency bands. The cell range at macro cellular layer varies from 150 to 3000 m, except one case, while for small cells it varies from 25 to 300 m.

In order to select the appropriate reuse pattern, K, and the appropriate frequency band, radio and network optimization aspects, like the analysis of cell coverage distance (or cell radius), co-channel reuse factor (ratio between the reuse and coverage distances), K, and supported throughput are addressed in this work for several levels of LTE MCS.

A. Analytical Formulations

If one considers the interference-to-noise ratio, M, defined by the ratio between the interference and noise powers, $M=I/N$, and the equation for the carrier-to-noise-plus-interference ratio (CNIR) to be used in the dimensioning process is the following:

$$\left(\frac{C}{N+I}\right) = \left(\frac{C}{N}\right)_{min} \quad (1)$$

equation (1) can be re-written in the two following ways:

$$\left(\frac{C}{N}\right) = \left(\frac{C}{N}\right)_{min} (1+M) \quad (2)$$

$$\left(\frac{C}{I}\right) = \left(\frac{C}{N}\right)_{min} (1+M^{-1}) \quad (3)$$

In (1) one is considering the model for CNIR from [5] while assuming that weights for noise and interference are the same. The interference-to-noise ratio is defined by

$$M(R) = \left(\frac{\left(\frac{C(R)}{N}\right)}{\left(\frac{C}{N}\right)_{min}}\right) - 1 \quad (4)$$

where $C(R)=P_R(R)$ is computed by applying, e.g., the ITU-R propagation model from [6]. Values of $M(R)$ are proportional to interference still tolerable for a given coverage distance, R, while (still) agreeing with the quality requirements for a given MCS.

With hexagonal cell topologies for the macro and pico cellular layers, in the DL, as shown in Figure 1, C/I is given by:

$$\frac{C}{I} = \frac{1}{2(r_{cc}+1)^{-\gamma}+2r_{cc}^{-\gamma}+2(r_{cc}-1)^{-\gamma}} \approx \frac{r_{cc}^{\gamma}}{6} \quad (5)$$

where r_{cc} is the co-channel reuse factor, given by $r_{cc}=D/R$, D is the reuse distance and R is the coverage distance (N.B. different Ds and Rs are defined for the macro and pico- cellular layers). In dB, the approximate equation is therefore $C/I \approx 10\cdot\gamma\cdot\log_{10}(r_{cc}/6)$.

By replacing (5) into (3), it is possible to obtain the following equation for the reuse factor in the DL:

$$r_{cc} = \sqrt[\gamma]{6\cdot\left(1+M^{-1}\right)\cdot\left(C/N\right)_{\min}} \quad (6)$$

As a horizontal asymptote arises in the analysis of the curves of r_{cc} as a function of the coverage distance, R, it is important to present the mathematical details associated to it. To compute the horizontal asymptote in the chart from $r_{cc}(R)$, one has to consider that $R \to 0$. Note that reuse pattern is given by $K=r_{cc}^2/3$.

From equation (6), if $R \to 0$ then $M \to +\infty$, and $M^{-1} \to 0$. For the DL, in the limit, one obtains:

$$\lim_{R\to 0} r_{cc} = \sqrt[\gamma]{6\cdot\left(C/N\right)_{\min}} \quad (7)$$

By considering the dependence of K on r_{cc}, it is straightforward to conclude that, for each value for the propagation exponent, apart from the dependence on the cellular interference geometry, K only depends on MCS through the corresponding minimum carrier-to-noise ratio.

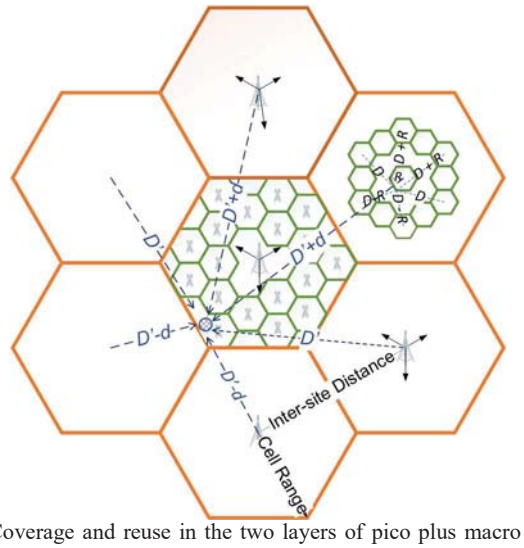

Fig. 1. Coverage and reuse in the two layers of pico plus macro HetNet, where co-channel interference s represented in the worst-case for the DL.

While the asymptotic reuse factor, r_{cc}, is associated with the upper bound for system capacity, the maximum coverage distance is associated with the carrier-to-interference-plus-noise ratio at the cell boundary when the interference is null. The vertical asymptote, $R_{asymptote}$, from $M(R)$ and $r_{cc}(R)$ represents the interference that can still be tolerated for a given R, in the limit, the maximum coverage distance for which no extra interference is tolerated.

B. Interference-to-noise Ratio and Co.channel Reuse Factor

By considering $R_{asymptote}=R_{M\to 0}$, one obtains the curves for the DL interference-to-noise ratio, considering the macro and micro/ picocellular scenarios from ITU-R model [6] for the 800 MHz and 2.6 GHz frequency bands, respectively. For the micro /picocellular scenario, the considered height from the macro base station is h_{BS}=10 m. For the macrocellular scenario, the height of the macro eNB is 25 m. The height of the mobile user is always h_{UT}=1.5 m. Variables $h'_{BS[m]}=h_{BS}$-1 and $h'_{UT[m]}= h_{UT}$-1 also stand. At 800 MHz, the breakpoint distance is $d_{BP}=4\cdot 24\cdot 0.5\cdot 800\cdot 10^6/c=$ =128m, where c is the velocity of light. For the 2.6 GHz frequency band, $d_{BP}=4\cdot 9\cdot 0.5\cdot 2.6\cdot 10^9/c$=156m. By considering these assumptions, in LoS, at 800 MHz, the path loss, PL, in dB is given by: $PL(d)=22.0\cdot\log_{10}(d_{[m]})+26.0618$, for d<128 m, and $PL(d)=40\cdot\log10(d_{[m]})-11.819$, for $d\geq$128 m. Also in LoS, at 2.6 GHz, for d<156 m, $PL(d)=22.0\cdot\log_{10}(d_{[m]})+36.29947$, while for $d\geq$156 m one achieves $PL(d)=40\ \log_{10}(d_{[m]})-3.12788$. In NLoS, the considered street width considered is 20 m while the average building height is 20 m. In the NLoS PL model there is no breakpoint. At 800 MHz, $PL(d)=39.08639\cdot\log(d_{[m]})+11.6067$ while at 2.6 GHz one achieves $PL(d)=36.7\cdot\log_{10}(d_{[m]})+33.48$.
Considering the values for P_t, G_t, G_r, BW and N_f from Table III, we obtained values for interference-to-noise-ratio, M, in the DL for f = 800 MHz. $M(R)$ depends on the CQI value and the MCS associated to it. Apart from the mapping between the MCS index and minimum CNIR, $CNIR_{min}$, Table I presents the corresponding values for the vertical asymptote, $R_{asymptote}$, for macro cells operating at 800 MHz and for pico cells operating at 2.6 GHz (LoS/NLos). At 800 MHz, one only discusses results BW=10 MHz, as the distances for the vertical asymptotes for BW=20 MHz are only slightly shorter. However, for the 2.6 GHz case, one also addresses results for BW=20 MHz. A relevant decrease of the values for the vertical asymptote (maximum R) occurs as the MCS increases because of the lowest associated $CNIR_{min}$.
Charts for the interference-to-noise ratio, $M(R)$, and reuse factor, r_{cc}, are shown in Figures 2-3 for the 800 MHz frequency band ($0\leq R\leq 3000$ m) for BW=10 MHz. Values from r_{cc} span from circa 1 up to 12 while the MCS order increases. Although charts for BW=20 MHz are not presented here, values of M are slightly lower than for BW=10 MHz, because of the highest noise power. Consequently, Rs for the vertical asymptotes are slightly shorter for BW=20 MHz. The chart of r_{cc} is also not presented because, apart from the shortest Rs for the asymptotes, the results for BW=20 MHz are very similar to the ones from Figure 3. From this analyses it is possible to conclude that the highest order MCSs can only be supported with high r_{cc} (hence high K).

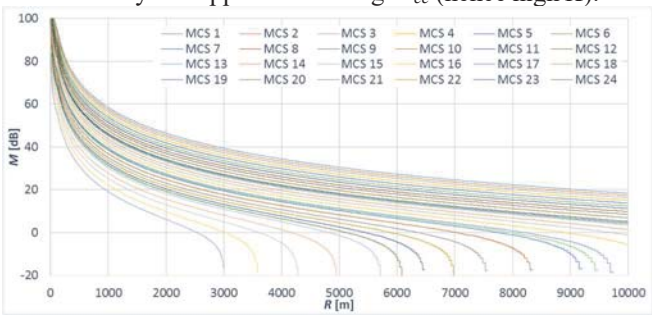

Fig. 2 Interference to noise ratio as a function of the coverage distance with MCS as a parameter for DL, in the 800 MHz band, BW = 10 MHz.

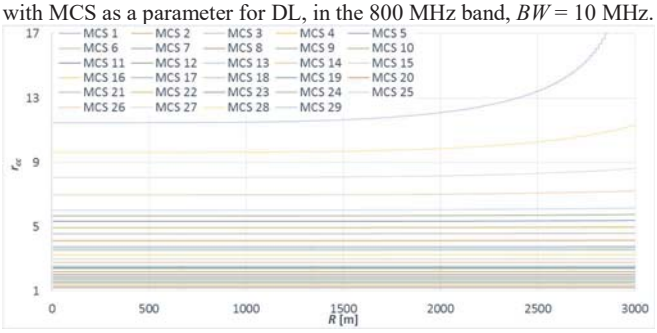

Fig. 3 Co-channel reuse factor as a function of the coverage distance with MCS as a parameter for DL, in the 800 MHz band, LoS, BW= 10 MHz.

Figures 4-5 analyse the case of 800 MHz band, NLoS, BW=10 MHz. The vertical asymptotes are clearly shorter. However, as the propagation exponent is 3.909, instead of 4, the behaviour of r_{cc} for the shortest distances is similar to the one from LoS case. Figure 6 presents the variation of $M(R)$ for the pico cellular layer, 2.6 GHz-LoS. The breakpoint is clearly visible for R=156 m. The shortest R for the vertical asymptotes occurs for R=488 m (MCS 29); hence, no vertical asymptote is visible for Rs up to 300 m.

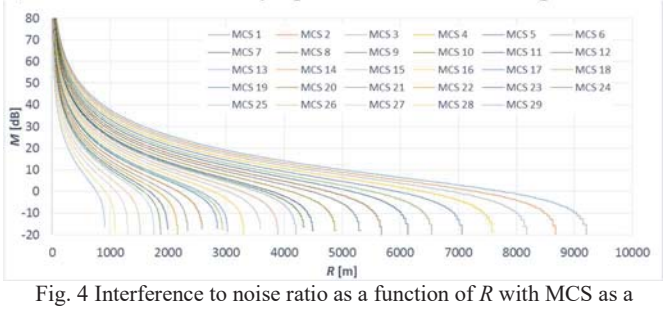

Fig. 4 Interference to noise ratio as a function of R with MCS as a parameter for DL, in the 800 MHz band, NLoS, BW = 10 MHz.

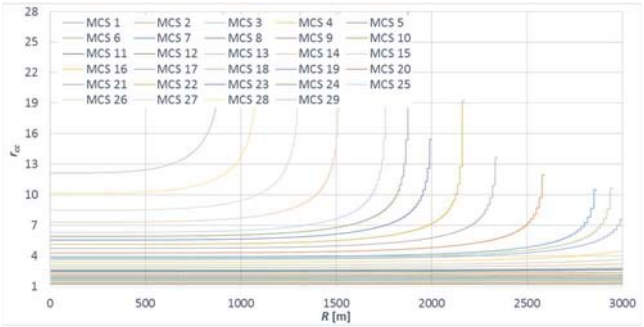

Fig. 5 Co-channel reuse factor as a function of the coverage distance with MCS as a parameter for DL, in the 800 MHz band, NLoS, BW = 10 MHz.

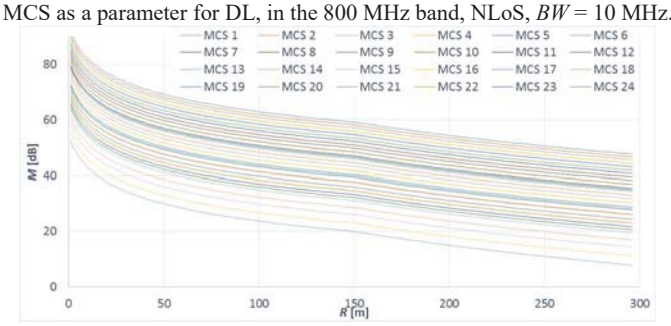

Fig. 6 Interference to noise ratio as a function of R with MCS as a parameter for DL, in the 2.6 GHz band, LoS, BW = 10 MHz.

Although the chart for r_{cc} is not presented here, the horizontal asymptotes for r_{cc} are the same as for the 800 MHz band, LoS as the propagation exponent is also γ=4. For BW=20 MHz, M is slightly lower (resulting in shorter asymptotes).

In the case of 2.6 GHz-NLoS, the propagation exponent is γ=3.67 and the path loss additive constant is higher than before. M is lower, and the asymptotes become visible in the range of Rs up to 300 m. Besides, an increase in r_{cc} exists. There are limitations in the coverage with the highest MCSs for the shortest Rs. For BW=20 MHz vertical asymptotes are slightly shorter compared to BW=10 MHz, resulting in worst coverage for short distances.

C. CNIR as a Function of r_{cc} with R as Parameter

Figure 7 facilitates to analyse the variation of the CNIR with r_{cc}, with R as parameter. Different frequency bands are considered as well as LoS versus NLoS propagation. When the interference power is much higher than noise power, the CNIR is given simply by $C/I \approx r_{cc}^{\gamma}/6$ in linear terms. In the analysis from Figure 7, this occurs in the majority of the cases, as interference, I, is always much higher than noise, N, i.e., M>8-10 dB, except for the cases "2.6 GHz-NLoS-R=300 m" and "800 MHz-NLoS-R=750 m", where M<8 dB for $r_{cc}\geq$2.85 and $r_{cc}\geq$8.75, respectively.

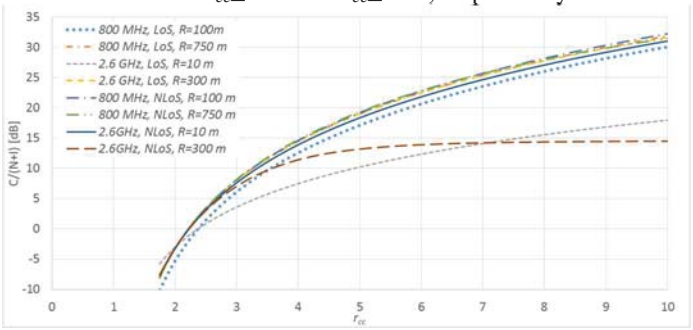

Fig. 7 Variation of the CNIR with r_{cc} for the DL in the 800 MHz and 2.6 GHz frequency band, LoS versus NLoS, and BW=10 MHz.

Hence, in the general case, the curves just follow the trend $10\cdot\gamma\log10(r_{cc}/6)$. From propagation models, one can observe that γ varies from 3.67 to 4, except for distances below the breakpoint. The exception occurs in the "2.6 GHz-LoS-R=10 m" case (purple dashed curve). In the "2.6 GHz-LoS-R=10 m" case, for the purpose of C/I computation, the value of γ is 2.2 (the lowest γ in our analysis). Also in the "800 MHz-LoS-R=100 m" case γ is considered to be 2.2 – but just for coverage purposes.

When the system is noise limited (clearly the case "2.6 GHz-NLoS-R=300 m" for $r_{cc}\geq$2.85, red wine dashed curve) $CNIR(r_{cc})$ follows a trend different from the one represented by $C/I \approx r_{cc}^{\gamma}/6$. Furthermore, if R increases for several hundreds of meters or even some kilometres, the distance considered in the computation of interference, i.e., reuse distance ($D=r_{cc}\cdot R$), considerably increases and interference decreases. Interference becomes therefore comparable to noise (not much high than noise anymore). Hence, the curves of CNIR would become lower than the upper limit curve. It is also a worth mentioning that the mapping between these values of CNIR and R_b are obtained by considering the correspondence from Table I (or Table II, in a simpler approach).

III. Detailed Analysis of System Capacity

While previous Sections analysed the individual influence of each MCS, it is also worthwhile to study the overall impact of several MCSs. Following the formulation from [7] for an implicit function procedure to compute supported throughput, the LTE system capacity is analysed for both macro (800 MHz) and pico (2.6 GHz) cellular layers from a Hetnet, considering the ITU-R propagation model [6]. The analysis considers different values of the reuse pattern, e.g., K=1, 3 and 7. One considers the values for P_t, G_t, G_r, BW and N_f from Table III. To map $CNIR_{min}$ into supported throughput one has assumed the values from $CNIR_{min}$ provided by [3], more specifically Tables 7.1.7.1-1 and 7.1.7.2.1-1. By extrapolating the gathered information it is possible to map the CNIR into MCS index, Modulation Order Transport Block Size (ITBS) index and TBS. Furthermore, by assuming TTI=1 ms the PHY throughput is obtained by multiplying the TBS by this value, and e.g., if 5 MHz bandwidth is considered, i.e., 25 PRBs, column NPRB=25 from Table 7.1.7.2.1-1 from [3] is assumed. This relation is presented in p. 122 from [7] (for BW=5 MHz), and in the last column from Table I (for BW=10 MHz), and similar relation exists for BW of 20 MHz. The maximum achievable number of coverage rings and MCSs are equal, i.e., 29, as each corresponds to different value of the PHY throughput. Figures 8 and 9 analyse the variation of CNIR and R_b with the distance d from cell centre to UE within a cell, where $0\leq d\leq R$, as shown in Figure 1. Respective cell sizes are R= 3000 and 300 m, at 800 MHz and 2.6 GHz, respectively, for BW=10 MHz, K=7;3. In "NLoS", CNIR and throughput are clearly lower than in "LoS". For the macro cellular layer, the curve for CNIR for reuse pattern 3 (r_{cc}=3) is clearly lower than for K=7 (r_{cc}=4.58) because of the much higher interference, resulting from the shortest D. This is evident both considering the LoS or NLoS propagation. The behaviour shown in Figure 9 for the pico cellular layer is similar to the one from Figure 8 (i.e., macro cellular layer).

For both (pico and macro) scenarios, by considering the mapping between $CNIR_{min}$ and R_b we clearly observe that the stepwise throughput is close to the maximum near cell centre, and gradually descends for longer distances (while UE approaches the cell edge). This decrease is more evident for NLoS propagation.

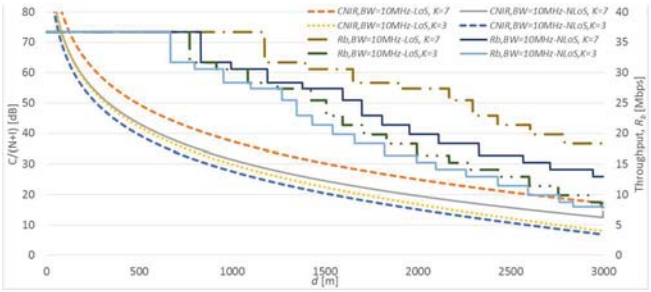

Fig. 8 Comparison of CNIR and R_b between K=7 and 3 for the macro cellular scenario (f=800 MHz), BW=10 MHz, and LoS versus NLoS.

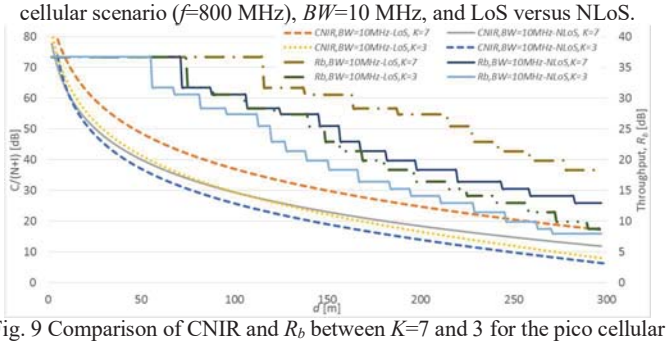

Fig. 9 Comparison of CNIR and R_b between K=7 and 3 for the pico cellular scenario (f=2.6 GHz), BW=10 MHz, and LoS versus NLoS.

Although the comparison of the behaviour between bandwidths of 10 and 20 MHz is not presented in these charts, the wider bandwidth is the lower is CNIR. From the results, this evidence is clearer for NLoS propagation but only slightly noticed for LoS propagation, as $N<<I$ and interference becomes dominant.

Figure 10 analyses the equivalent supported throughput, $R_{b\text{-}sup}$, as a function of R, for pico cells with size up to 300 m and macro cells with size up to 3000 m. $R_{b\text{-}sup}$ is determined through a weighted sum of the PHY throughput in each coverage ring throughout the cell, where the weights are the individual areas of each of the coverage rings. Bandwidth is 10 MHz. $R_{b\text{-}sup}$ is clearly superior for K=7 (blue curves) and lower for K=3 (green, red and purple curves). The curves for pico cellular scenario are the dashed ones while the continuous curves show throughput in the macro cellular scenario. At 2.6 GHz (pico cells), as there is no breakpoint in the model for NLoS, the curves (light blue and dark green) have regular behaviour. A noticeable behaviour is thus the decrease in $R_{b\text{-}sup}$ that occurs for the largest Rs, a characteristic from dynamic MCS. As the relevant model for LoS propagation at 2.6 GHz has a breakpoint at 156 m, the behaviour of CNIR changes when either the values of R or $D=r_{cc}.R$ reach d_{BP}=156 m. This means that changes in behaviour occur for $R_0= d_{BP}/r_{cc}$, i.e., R_0=52 m for K=3 and R_0=34 m for K=7, as well as for $R=d_{BP}$.

For $R<d_{BP}/r_{cc}$ the propagation exponents considered in the computation of $C(R)=P_R(R)$ and I are the same (γ=2.2), while for $R_0\leq R\leq$156 m the propagation exponent to compute I is already 4 while the coverage is still computed with γ=2.2. Hence, because of the resulting less interference in this range of Rs, a significant increase into the maximum achievable $R_{b\text{-}sup}$ is achieved, facilitating the optimization of SC networks. This analysis gives very useful hints for the optimization of CA [5], [7] between macro and pico cellular layer of a LTE-A HetNet with outdoor pico cells as trade-offs associated with the use different Ks are highlighted for LoS/NLoS propagation conditions. Although the charts do not analyse the wider values for bandwidth, the results we achieved in such analysis show that, despite the slight decrease in CNIR, circa twice of the capacity is achieved.

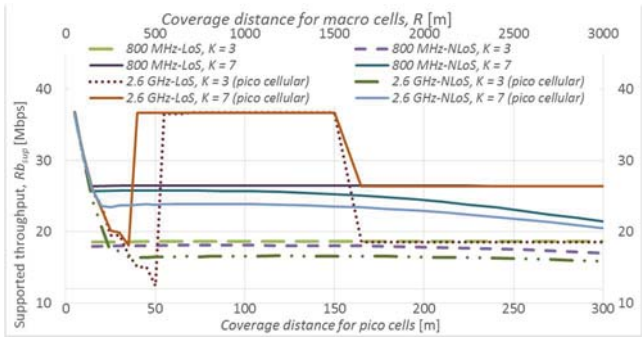

Fig. 10 Comparison of the equivalent supported throughput between K=7 and 3 for the pico/macro cellular scenarios and LoS/NLoS, BW=10 MHz.

IV. Conclusion

For cellular radio and network optimization purposes, the UL and DL carrier-to-noise-plus-interference ratios (CNIRs) from/at the mobile station are very important parameters. From a detailed analysis of its variation with the coverage and reuse distances for different LTE-A system parameters, modulation and coding schemes, in the DL, and ITU-R propagation models, an evaluation of the possible range for the reuse pattern has been performed. By considering the MCS and reference CNIR requirements recommended by 3GPP, DL peak bit rates along with the Transport Block Size assumed for single stream and bandwidths of 10 MHz and 20 MHz, an analysis of the physical and supported throughputs has been performed. One can learn that one common characteristic of the two frequency bands is the clear decrease of the supported throughput over the coverage distances with NLoS propagation. Besides, for the small cell layer, operating at 2.6 GHz, owing to the behaviour of the two slope model in LoS propagation conditions (where a breakpoint distance, d_{BP}, exists), a maximum occurs for system capacity for coverage distances, R, in the range between d_{BP}/r_{cc} and d_{BP}, a noticeable finding from this research.

***Abstract*—This paper discusses key enabling technologies to realize wide area and mobile communication systems based on IEEE 802.15.4g wireless smart utility network (Wi-SUN) that is mainly used for advanced metering infrastructure. Firstly, three applications of the wide area and mobile communication systems are proposed. Then, transmission performance is evaluated by using propagation characteristic models for the three applications. Service areas of the communication systems are then estimated. Secondary, the service area calculation is validated by using actual Wi-SUN certified IEEE 802.15.4g modules. Thirdly adoption of maximum ratio combining diversity technique is proposed for the IEEE 802.15.4g based wide area and mobile communication systems. Then extension of the coverage area by the technique is evaluated by computer simulation.**

Keywords—IEEE 802.15.4g, Wi-SUN, mobile communication, , Sensor network, Smart Utility Network

I. INTRODUCTION

Currently there are increasing demands for Wi-SUN (Wireless Smart Utility Network) communication systems. In the systems, Electricity/Gas/Water meters equipping SUN (Smart Utility Network) radio devices can effectively automatically relay data frames to the collection station by expanding its service area. The SUN system also controls energy consumption according to the collected data [1]. The Wi-SUN is based on IEEE 802.15.4g that defines an alternate physical layer specification for principally outdoor Low Data Rate Wireless Smart Metering Utility Network [2][3]. It also includes additional specifications of MAC, adaptation, network, and transport layers' profiles in order to support several applications such as energy management. Currently the Wi-SUN alliance [3] has standardized its specification with interoperability between venders. One of the achievements of the Wi-SUN profile is the specification for Japanese Electricity companies. The specification is for the communication between smart meter and HEMS (home energy management system). All electricity companies in Japan have adopted the specification and the number of its subscribers is more than several tens million. After the success, new application fields for the Wi-SUN are being considered. Agriculture, disaster prevention, and intelligent transport systems have currently been proposed.

Considering new applications such as agriculture and disaster prevention, the coverage area should be as large as possible. The regulation in Japan for IEEE 802.15.4g is the following. The maximum transmission power for license-exempt is 20 mW and the operational frequency band is 920 MHz band. In this case the transmission range is at most 500 m when omni-directional antenna is used. If the range is larger than several km and the Wi-SUN supports mobile communications, a system design same as mobile phone system may be available.

This paper discusses key enabling technologies to realize wide area and mobile communication systems based on IEEE 802.15.4g Wi-SUN. Firstly, three applications of the wide area and mobile communication systems are proposed. Then, transmission performance of the Wi-SUN system under the new applications is evaluated by using propagation characteristic models for the three applications. Service areas of the communication systems are then estimated. Secondary, the service area calculation is validated by using actual Wi-SUN certified IEEE 802.15.4g modules. Thirdly adoption of maximum ratio combining diversity technique is proposed for the IEEE 802.15.4g based wide area and mobile communication systems. Then extension of the coverage area by the technique is evaluated by computer simulation.

II. CATEGORY OF WIDE AREA MOBILE WI-SUN SYSTEM

Fig. 1 and Table 1 categorize the wide and mobile communication systems based on Wi-SUN into three. Category (a) is an information sensing and monitoring system in wide area open space environment. The category is based on fixed point-to-multipoint communication and its coverage area is 1-5 km. In Fig. 1, each sensor and/or monitor communicates with access points (APs). Fig. 2 shows three configurations of APs.

AP (i) is based on a Wi-SUN certified IEEE 802.15.4g module. The module may divide into two: transmission part and reception part. The reception part may have a function of diversity such as maximum ratio combining (MRC) diversity. AP (ii) is based on several Wi-SUN certified IEEE 802.15.4g modules. Some of them may be used for diversity reception. AP (iii) is based on a software-defined radio that consists of multiband RF units for transmission and reception and a reconfigurable signal-processing unit (SPU).

Category (b) is an information sensing and monitoring system in wide area urban environment. APs are equipped on the building and communicate with sensors and/or monitors equipped in houses and/or shops by Wi-SUN. The communication is mainly non-line-of-sight and therefore the

direct communication between APs and sensors/monitors may not be available. In this case, we may use Wi-SUN routers shown in Fig. 3. The router is a bridge between Wi-SUN and short-range wireless (SRW) communication systems such as Wi-SUN, Bluetooth, and NFC.

Category (c) is an information sensing and monitoring system in wide area mobile communication environment. APs are equipped on the building and communicate with sensors or monitors equipped in vehicles such as car and bus.

III. Design of Wide Area Mobile Wi-SUN Communication Systems

A. *Simulated transmission performance of IEEE 802.15.4g compliant Wi-SUN system*

Transmission performance of IEEE 802.15.4g compliant Wi-SUN system is evaluated by computer simulation. Figs. 4 and 5 and Table 2 show configuration, frame format, and specification of IEEE 802.15.4g transmitter, respectively. Table 3 shows parameters used in the computer simulation. Recursive and systematic code (RSC) shown in Fig. 6 is used in the simulation [2]. As propagation characteristic models, one path Rayleigh fading model and COST 207 GSM typical urban (TU) model shown in Table 4 are used [4]. Figs. 7 and 8 show the relationship between SNR (Signal-to-noise ratio) and PER (Packet Error Rate) under AWGN and fading environments, respectively. In Fig. 8 vehicle speeds of 0, 4, and 40 km/h are used. The required PER in IEEE 802.15.4g is 10^{-1} in the IEEE 802.15.4g standard when packet payload length is 250 octets. The required SNR to achieve the required PER is summarized in Table 5. The table shows that IEEE 802.15.4g cannot achieve the required PER when GSM typical urban model is used as fading model and the vehicle speed is 40 km/h.

Table 2 Basic specification of IEEE 802.15.4g.

Frequency	920 MHz

	Relative power [dB]	-3	0	-2	-6	-8	-10

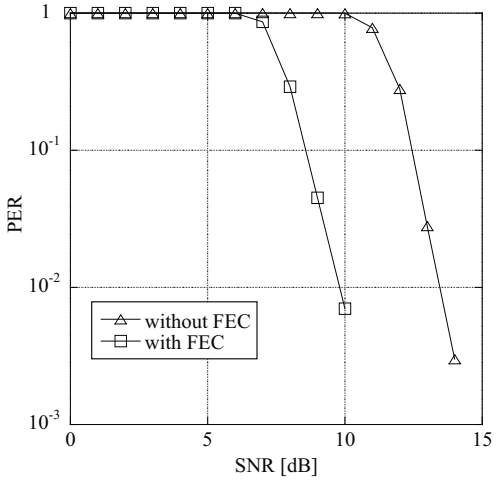

Fig. 7 PER performance (AWGN).

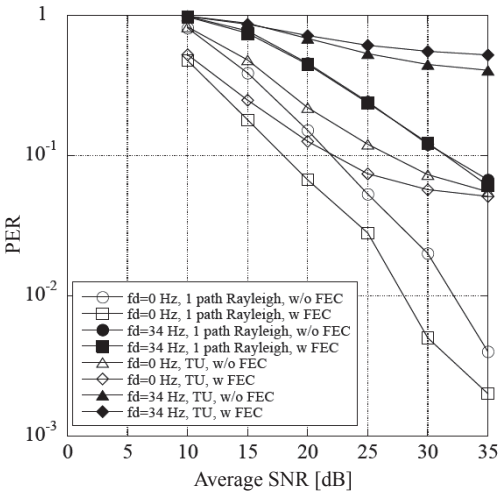

Fig. 8 PER performance (Fading environment).

B. Estimation of communication area

By using the result in Table 5, the communication area is calculated. The authorized maximum transmission power in 920 MHz band is 20 mW for license-exempt radio equipment and 250 mW for registered radio equipment. In our proposed systems shown in Fig. 1, each AP has a 250 mW radio equipment and each terminal has a 20 mW one. In this case transmission power difference between AP and terminal is 11 dB. This means that transmission distance of uplink is dominant to decide communication area. To keep same transmission distance between uplink and downlink, an AP has several directional receiving antennas as shown in Fig. 2. In this paper communication area of uplink is calculated by using parameters in Table 6. The received SNR, SNR_r at AP in uplink is calculated as following.

$$SNR_r = P_T + G_{AP} + G_T - L_f - (N_{AP} + N_s) \qquad (1)$$

where P_T, G_{AP}, G_T, L_f, N_{AP}, and N_s are transmission power of terminal, antenna gain of AP, antenna gain of terminal, propagation path loss and system noise in the receiver of AP, respectively. Table 5 also summarizes the acceptable L_f to achieve SNR_r equal to the required SNR that achieves PER= 10^{-1}.

Table 5 Required SNR and L_f to achieve PER = 10^{-1}.

Fading model	1 path Rayleigh		GSM typical urban	
Maximum Doppler frequency [Hz]	0	34	0	34
Required SNR to achieve PER of 1.0e-1 (w/o FEC)	22	32	27	N/A
Required SNR to achieve PER of 1.0e-1 (w FEC)	18	32	23	N/A
Acceptable path loss (w/o FEC) [dB] (UL)	116	106	111	N/A
Acceptable path loss (w FEC) [dB] (UL)	120	106	115	N/A

Table 6 System parameters.

	DL	UL
Transmission power of AP	24 dBm	
Transmission power of terminal		13 dBm
Antenna gain of AP	3 dBi	6 dBi
Antenna gain of terminal	3 dBi	3 dBi
Noise power (thermal noise)	−120 dBm	−120 dBm
Additional system noise level to thermal noise	+5 dB	+5 dB
Bandwidth/ch	200 kHz	200 kHz

In the case of category (a) in Fig. 1, the typical antenna height is 4 m and Okumura-Hata propagation model is adopted. The typical antenna height is 30 m in the case of categories (b) and (c) and Walfish-Ikegami propagation model is adopted. The relationship between distance and propagation path loss is shown in Fig. 9. In this calculation, the antenna height of AP and terminal is 30 m and 1.5 m, respectively. Moreover, the width of road and the interval of building and the angles of road and path between AP and terminal are 10 m, 10 m, and 0, 45, 90 degrees, respectively.

Table 5 and Fig. 9 show that the maximum communication area is 2 km and 500 m in the case of Category (a) and Category (b), respectively when the multipath model is one path Rayleigh fading.

C. *Experimental transmission performance by IEEE 802.15.4g compliant Wi-SUN module*

To do validation of estimation of communication area, transmission performances under AWGN environment and multipath fading environment are measured by using IEEE 802.15.4g compliant and Wi-SUN certified modules as shown in Fig. 10. In the laboratory experiment, two radio modules and a fading emulator are used and the PER performances are measured. Table 7 summaries parameters used in the experiment. Figs. 11 and 12 show PER performances in AWGN and multipath fading environment, respectively. Table 8 summarizes the required RSSI to achieve 10^{-1} and also summarizes the acceptable L_f to achieve SNR_r equal to the required RSSI by using noise parameters shown in Table 6. By using Table 6 and Fig. 9, the communication area is calculated.

Table 6 and Fig. 9 show that the maximum communication area is 1 km and 300 m in the case of Category (a) and Category (b), respectively when the multipath model is one path Rayleigh fading.

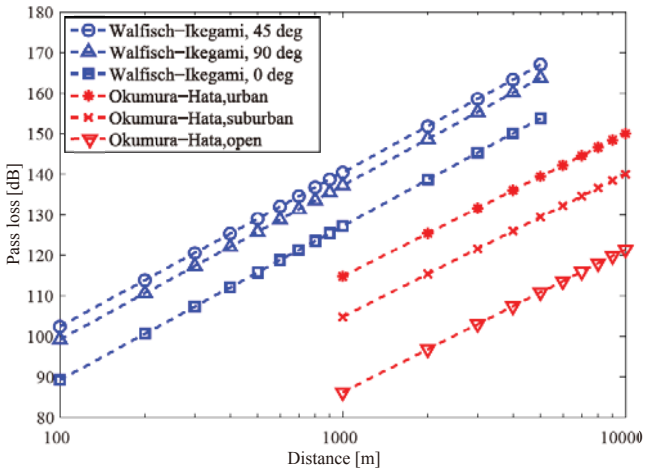

Fig. 9 Relationship between path loss and distance.

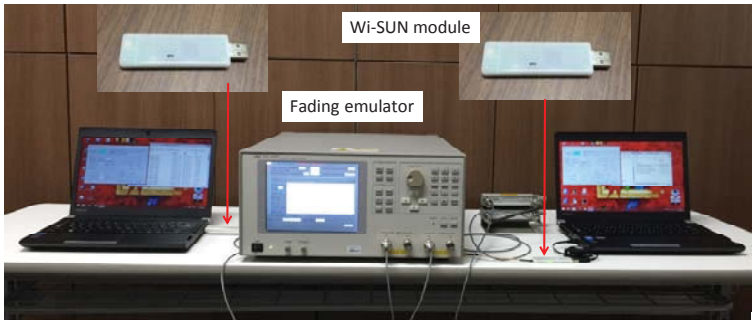

Fig. 10 Experimental environment.

Table 7 Parameters used in the experiment.

Compliant standard	IEEE 802.15.4g

Modulation index	1.0
Payload size	250 octets
Transmission rate	100 kbps
Data whitening	Off
CRC	CRC-32
Multipath fading model	1 path Rayleigh fading, GSM typical urban (COST207)
Maximum Doppler freq.	34 Hz, 0.4 Hz

IV. PROPOSAL FOR PERFORMANCE IMPLOBEMENT

To achieve communication area larger than 4 km, L_f must be larger than 125 dB (suburban) from Fig. 8 when Okumura-Hata model is used in the Category (a). In addition, L_f must be larger than 130 dB to achieve communication area of 1-2 km when Walfish-Ikeami model is used in the Categories (b) and (c).

To support L_f larger than 125 dB, the required SNR to achieve PER=10^{-1} must be smaller than the one in Figs. 8 and 12. The target of the required SNR is smaller than 14 dB. One of the technique is to use diversity reception, especially MRC reception. Fig. 13 shows PER performance of Wi-SUN when two-branch MRC reception is used. The figure shows that the required SNR is smaller than 14 dB when TU model is used and fd=3.4 Hz. And even if the maximum Doppler frequency is 34 Hz, the required SNR is 16 dB. This means that the communication area is expected to achieve greater than 1 km when transmission powers of AP and terminal are 250 mW and 20 mW, respectively in Category (a)-(c).

Fading model	GSM typical urban	
Maximum Doppler frequency [Hz]	3.4	34
Required SNR to achieve PER of 1.0e−1 (w FEC and MRC)[dB]	13	16
Acceptable path loss (w FEC and MRC) [dB] (UL)	125	122

V. Conclusion

This paper discussed key enabling technologies to realize wide area and mobile communication systems based on IEEE 802.15.4g Wi-SUN. Three applications of the wide area and mobile communication systems were proposed. Then, transmission performance was evaluated by using propagation characteristic models for the three applications. Service area of the communication systems was finally estimated. The results showed that the maximum communication area was 2 km and 500 m in the case of Category (a) and Category (b), respectively when the multipath model is one path Rayleigh fading. In the case of Category (c) and in the TU multipath fading environment it is very difficult to achieve PER=10^{-1}. But by using MRC diversity reception, the communication area was expected to achieve greater than 1 km when transmission powers of AP and terminal are 250 mW and 20 mW, respectively in Category (a)-(c). As further works, actual field experiment will be performed.

***Abstract*—The rise of opportunistic mobile phone sensing paradigm is due to ubiquitous mobile phones usage. Optimisation of battery energy consumption and achieving required spatial coverage of sensing area are important issues under opportunistic mobile phone sensing networks. Human mobility enable collection of mobile phones sensor data and sensing area coverage by forming communication network with surrounding neighbors devices (mobile phones). This paper proposes a human mobility based selective sensing framework called as HWSS (Human Walk based Selective Sensing) for sensor data collection in opportunistic mobile phone sensing networks. In proposed HWSS method, mobile phones are selected for sensing task based on users current and predicted future locations and sensing overlap area. The proposed HWSS method is compared with non-selective sensing method (NSS), where all mobile nodes are allowed for sensing during sensor data collection process, in an given application area. The simulation results show that compared to NSS method proposed HWSS method achieves reduction in energy consumption and required spatial coverage.**

***Index Terms*—Energy Consumption, Human Walk, Mobile Phones, Sensing area Coverage, Sensors**

I. Introduction

Mobile phones or smart phones which are usually carried by humans are coming with different types of scalar and multimedia sensors. For a mobile phone, sensors may be embedded externally or inbuilt, includes accelerometer, gyroscope, magnetometer, digital compass, temperature, light, proximity, barometer, humidity, heart rate, SpO2 (peripheral capillary oxygen saturation), camera, microphone and GPS (Global Positioning System) [1], [2]. Mobile phones are also come up with different types of communication technologies like 2G/3G/4G and near field communications (Wi-Fi, Bluetooth and RFID (Radio-frequency identification) [1], [2].

Mobile phone sensing applications include urban monitoring [3], [4], [5], environment monitoring, traffic monitoring [6], health care monitoring [7], intelligent transportation, disaster management [8], [9], mass education and social networking [3], [10], [9].

Human mobility enables collection of mobile phone sensor data by forming network with other device (mobile phones) in their communication range for sensing task. There are numerous open issues and research challenges to build up efficient mobile phone sensing network applications using embedded sensors and communication resources. Efficient usage of battery power, spatial and temporal sensing area coverage are challenging research issues in mobile phone sensing. Opportunistic and dynamic human mobility nature and their activities affect the performance of mobile phone sensing networks [11]. In opportunistic mobile phone sensing, mobile phones come in contact with other mobile phones and devices opportunistically [11].

For continuous environmental sensing applications using mobile phone sensors, consider high density of mobile phone users scenario, there is more possibility of spatial and temporal sensing area overlap. Mobile phone resources will be shared by many applications running on it. Sensing applications should not drain battery power and affect other applications running on it. Ensuring required minimal energy consumption and required spatial and temporal coverage of sensor data are fundamental issues in mobile phone sensing.

This paper refers to human mobility based selective sensing for efficient mobile phone sensor data collection in opportunistic sensing networks. Levy walk (LW) mobility model which depict the statistical properties of human walk patterns is considered for evaluation of proposed work. Reference [12], [13], [14], [15], [16], [17] explore LW mobility model.

Formation of communication network between mobile phones for sensing task requires regular lookup for neighbors, processing and exchange of messages, security and trust protocols. Hachem *et al.* [18] discusses reducing number of participatory users plus improving coverage by assuming that users are aware of their path. Sheng *et al.* [19] presents collaborative mobile phone sensing using cloud network. They also assume that mobile phone users path is known in advance.

In opportunistic mobile sensing applications, where users visit in the vicinity of application region is not frequent or dynamic in nature, prediction of users current location, velocity, movement direction, future location, duration of stay using mobile phone sensors is preferable [20] [21], [12], [22], [23], [24]. There is need to analyse the impact of unpredictable and opportunistic nature of human mobility on energy consumption, spatial and temporal coverage on mobile phone sensing applications.

This paper considers opportunistic mobility nature of mobile phone users and analyses the impact of dynamic human movements and patterns on energy consumption and sensing area coverage by considering proposed selective sensing method.

In proposed work, current and predicted future locations of mobile phone users used for selecting mobile phones to perform sensing task. There are many references [20], [21], [22] which explain how mobile phone users movement velocity, direction and angles can be obtained by using sensors like accelerometer, magnetometer, gyroscope and GPS in outdoor and indoor locations. In this paper, we assume that mobile phones use any method to calculate or to obtain their velocity, direction and angle of movement. The proposed work is compared with non-selective mobile phone sensing task, where all the mobile phones are involved in sensing and sending their sensed data to dedicated destination. The proposed selective sensing method achieves required spatial coverage and also shows reduction in energy consumption for mobile phone sensing activity.

The remainder of this paper is organized as follows. Section II describes system model for the proposed work. Section III gives description of proposed selective sensing algorithm for opportunistic mobile phone sensing. Section IV discusses evaluation of simulation results and Section V concludes the paper.

II. System Model

This section provides the description of models used for the development of proposed selective sensing framework for opportunistic mobile phone sensing networks.

Let A be the area of application, which consists of p number of mobile phone users. Mobile phones are also termed as mobile phone users or mobile nodes. For performance analysis of proposed work LW mobility model given in [14] is used. Mobile nodes are categorised into two types. One is mobile sensing ms nodes, which are embedded with GPS for getting location co-ordinates and other application related sensors. Another type of mobile nodes are called as volunteer mobile vm nodes, which are embedded with GPS and may or may not come with other application related sensors.

Let ms_i represent i^{th} mobile sensing node, where $i = 1, 2, ...n.$ and let vm_c represent c^{th} volunteer mobile node, where $c = 1, 2, ...m$ and n+m=p.

Let r_j be the sensing range of j^{th} sensor which is attached to i^{th} ms node, where $j = 1, 2, ...k$. We consider disk model for sensing range. Let t_j be the sampling interval of j^{th} sensor. When a mobile node moves in a straight line path with constant velocity cv and without pause or change of direction, then t_j for non-overlap sensing coverage with respect to j^{th} sensor is given by [25]:

$$t_j = 2 * \frac{r_j}{cv} \tag{1}$$

Let average or preferred human walk velocity be hwv. Under LW mobility model equation (1) is given by [25]:

$$t_j = 2 * \frac{r_j}{hwv} \tag{2}$$

III. Description of Proposed Selective Sensing Framework

It is assumed that a Dedicated Base Station (DBS) is responsible for sensor data collection from all the vm nodes and has dedicated control and sensor data collection channel. It is considered that vm nodes are programmed to send and receive query from a Dedicated Base Station (DBS). DBS broadcast query to vm nodes requesting their current location. Based on the reply from vm nodes, DBS selects specific vm node in the required application region. Multiple vm nodes can be selected but there should not be any overlap between the communication range of vm nodes for considered application time.

On receiving the command and information from DBS selected vm nodes initiate sensor data collection task with ms nodes. The pseudocode for collecting sensed data from ms nodes is given in Algorithm 1. For simplifying the performance analysis of proposed work under human mobility model, we assume collection of single sensor data from ms nodes.

For given simulation duration T, total number of sensor data collection iterations R is given by equation (3), where t_j is the sampling interval of a considered sensor (equation (2-3)). The proposed sensor data collection algorithm given in Algorithm 1 is repeated for every t_j duration until given time T. At the start of each iteration I where $I = 1, 2, ..., R$, vm computes eligible ms nodes for sensing task. The brief description of each step (Algorithm 1) is given in following subsections.

$$R = \frac{T}{t_j} \tag{3}$$

Algorithm 1 :Pseudocode for sensor data collection from ms nodes

1: **for** $I \leftarrow 1, R$ **do**
2: vm broadcast req_{info} packet to ms nodes.
3: ms nodes reply by sending requested data to vm through $replay_{info}$ packet.
4: vm computes the eligible ms nodes for sensing task and broadcast req_{sense} packet.
5: Selected ms nodes transmit sensed data within time assigned by vm.
6: **end for**

A. Broadcasting req_{info} packet

The selected vm node from DBS broadcasts req_{info} packet to ms nodes. In general, req_{info} packet consist of $[addr_{vm}, I, cur_loc_{vm}, req_addr_{ms}, req_curr_dir_info, req_sensor_info, req_velo]$. $addr_{vm}$, I and cur_loc_{vm} indicates vm node address, sampling iteration number and current vm node location respectively. req_addr_{ms}, $req_curr_dir_info$, req_sensor_info and req_velo represents address of ms, direction related sensors information, other sensors information (sensor type and range), and current velocity. These are the parameters required by vm to select the eligible ms nodes for sensing task.

B. Sending $reply_{info}$ packet by ms nodes

On receiving broadcasted req_{info} packet, ms nodes compute required data which are specified by vm node and reply by sending $reply_{info}$ packet. $reply_{info}$ packet consists of $[addr_i, I, (xc_i, yc_i), curr_dir_info_i, \{sensor_type_j, r_j\}, curr_velo_i]$.

C. Broadcast req_{sense}

On receiving $reply_{info}$ packet from ms nodes which are sent within some t_{parm} time, vm computes the eligible ms nodes. The pseudocode for selecting eligible ms nodes for sensing task is given Algorithm 2.

Algorithm 2 :Pseudocode for selection of ms nodes

```
compute current overlap between ms nodes
compute future overlap between ms nodes
if (current overlap between any pair of ms nodes > π*r_j^2/3
    and predicted future overlap > π*r_j^2/1.6) then
    remove any one ms node and mark another ms node as eligible node
else
    Mark both the ms nodes as eligible nodes
end if
```

For simulation of proposed work, direction of LW mobile nodes is calculated from their location traces.

Let (xc_i, yc_i) and (xp_i, yp_i) be the current and previous location co-ordinates at time t_2 and t_1 respectively where $t_1 < t_2$. Equation (4) gives the general formula for calculating direction angle of any i^{th} ms node.

$$\phi = \tan(yp_i - yc_i, xp_i - xc_i) \tag{4}$$

General equation to calculate future location co-ordinates for i^{th} ms node at given time t_f is given in equation (5), where $t_f > t_1$.

$$\begin{aligned} xf_i &= xc_i + curr_velo_i * t_f * cos(\phi) \\ yf_i &= yc_i + curr_velo_i * t_f * sin(\phi) \end{aligned} \tag{5}$$

By using current location, calculated future location and sensor range r_j of ms nodes, vm node calculate overlap sensing area between each and every pair of ms nodes. For any pair of ms nodes, if sensing area overlaps between them is greater than 33% when current location is considered and greater than 62% for predicted future location, then any one of ms is marked as non-eligible and another node is considered as eligible sensing node. If sensing area overlap between any pair of ms nodes is greater than 62% for predicted future location, then any one of ms is marked as non-eligible and another node is considered as eligible sensing node. After finding the eligible nodes and non eligible nodes vm broadcast req_{sense} packet. req_{sense} packet consists of information like eligible, non-eligible ms node id's of corresponding I^{th} sampling iteration, t_j and time limit to send back the sampled sensor data. By declining the assignment of sensing task to non-eligible ms nodes, overall sensing area overlap and energy consumption for proposed method is reduced.

D. Transmission of Sensor Data

It is assumed that some amount of time $t_{outrange_node}$ (equation (6)) is spent by vm node after broadcasting req_{sense} packet to collect sensed data from ms nodes. Let ls and vm_{range} be the speed of light and vm node's communication range respectively. Within $t_{outrange_node}$ time, if a ms node has not transmitted its sensor data, then it is assumed that the node has moved out of communication range of vm node.

$$t_{outrange_node} > 2 * \frac{vm_{rage}}{ls} + t_j \tag{6}$$

IV. Simulation Results and Discussion

To simplify the performance analysis of proposed work, it is assumed that base station chooses a random vm node, which is within the range of 100 meters from center of application area A at time t_{vm}. It is assumed that within t_{start} $(t_{vm} < t_{start})$ time base station completes selection of vm node and sends the required information to start the mobile phone sensor data collection task. At time t_{start} selected vm node start sensor data collection routine (Algorithm 1.). The preferred human walk velocity hwv is $\approx$ 1.0 m/s [26].

For all ms nodes, sensor range is assumed to be 20 meters. Other considered simulation parameters are given in Table 1. Term NSS is used to represent non-selective sensing which allows all the ms node for sensing. In order to represent proposed human walk based selective sensing method we use term HWSS.

For given A, T, and p values, proposed mobile phone sensing method is analysed in terms of average units of energy consumption and spatial coverage (sensing area coverage). Better performance is needed in terms of reduction of energy consumption and also in terms of required spatial coverage.

Energy consumption and sensing area coverage is calculated for every iteration. For proposed method, energy consumption and sensing area covergae is represented by $HWSS_E_I$ and $HWSS_cov_I$ respectively. For NSS method, energy consumption and sensing area coverage is represented by NSS_E_I and NSS_cov_I respectively.

Let λ_HWSS_I and λ_NSS_I be the total number of sensor data samples sent to vm node from mobile nodes by HWSS and NSS methods respectively at I^{th} iteration.

Then non-overlap sensing coverage area for HWSS and NSS methods is given by equation (7) and (8) respectively.

$$HWSS_nv_cov_I = \pi * r_j^2 * \lambda_HWSS_I \tag{7}$$

$$NSS_nv_cov_I = \pi * r_j^2 * \lambda_NSS_I \tag{8}$$

For considered sensing methods, if their sensing coverage is greater or equal to respective non-overlap sensing coverage then the method is acceptable, i.e, considered sensing method has achieved required spatial coverage.

$$HWSS_cov_I \geq HWSS_nv_cov_I \tag{9}$$

$$NSS_cov_I \geq NSS_nv_cov_I \tag{10}$$

We assume one unit of energy is consumed for sensing (both GPS and sensor) and sending a sensor sample by a mobile

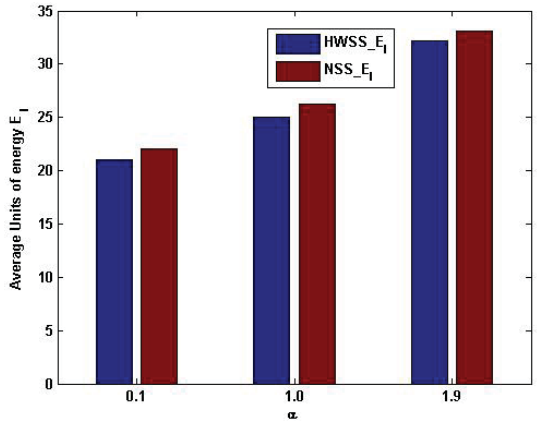

Fig. 1. Energy Consumption

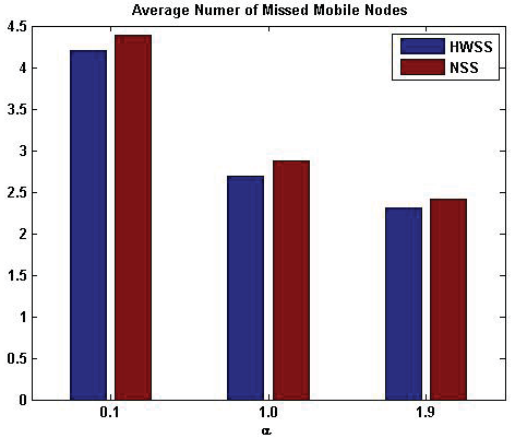

Fig. 2. Energy Consumption

node. Therefore, total energy consumed for proposed and considered sensing method is equal to the respective total number of sensor samples received by vm in I^{th} iteration.

$$HWSS_E_I = \lambda_HWSS_I \tag{11}$$

$$NSS_E_I = \lambda_NSS_I \tag{12}$$

First the impact of velocity of mobile nodes on energy consumption and sensing area coverage is analysed for both the proposed HWSS and NSS methods. Birand *et al.* [15] explore dynamic graph properties under LW mobility model. As LW mobility parameter α value decreases, $(0 < \alpha < 2)$, mobile networks become more dynamic and vice-versa [15]. For analysing the performance of proposed work α in LW mobility model is set to 0.1, 1.0 and 1.9 $(0 < \alpha < 2)$ for generating low, high and medium speed ms nodes respectively. Table 2 show average velocity of mobile nodes. For this considered simulation parameters are given in Table 1.

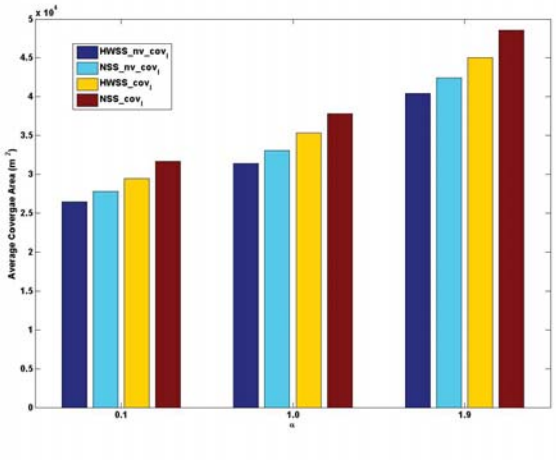

Fig. 3. Sensing Area Coverage

Figure 1 and 3 show average energy consumption and average sensing area coverage for different values of α. The simulation duration T is set to one hour, which is long enough to run many iterations. Other considered simulation parameters are given in Table 1. Dynamic network topology, i.e., when $\alpha = 0.1$, increases missing rate of mobile nodes (mobile nodes moving out of vm node range), thereby reducing number of sensor samples sent to vm node. Therefore when mobile phone nodes velocity is high i.e., for $\alpha = 0.1$ mobile nodes show very low coverage and energy consumption compared to $\alpha = 1.0$ and $\alpha = 1.9$ (Fig. 1 and Fig. 3). Low velocity mobile nodes lead to decrease in missing rate of mobile nodes (Fig. 2), as their incoming and outgoing rate within the application region is very slow. Therefore, when mobile phone nodes velocity is low i.e., for $\alpha = 1.9$ mobile nodes show very high coverage and energy consumption compared to $\alpha = 1.0$ and $\alpha = 0.1$ (Fig. 1 and Fig. 3). When mobile phone nodes velocity is equal to normal human walk velocity i.e., for $\alpha = 1.0$ mobile nodes show coverage and energy consumption in between to $\alpha = 0.1$ and $\alpha = 1.9$.

For proposed HWSS method, there is reduction of energy consumption (Fig. 1) for all the considered values of α. Because ms node are selectively chosen such that there should be less overlap between them. Both the sensing methods have achieved respective required sensing coverage area (Fig. 3). NSS covers much extra area then required and also energy consumption. In Fig. 3 the proposed HWSS method has also crossed required NSS method non-overlap sensing area coverage i.e., $HWSS_cov_I > NSS_nv_cov_I$. In each sensor data collection iteration I, simulation results show reduction in energy consumption for HWSS method. Even a single percent reduction of energy consumption for each iteration will save a lot overall network energy in long run of mobile phone sensing applications. Combining the results of Fig. 1 and Fig. 3, proposed HWSS method show better performance in terms of reducing energy consumption of mobile nodes and also

TABLE I
SIMULATION PARAMETERS

Simulation Area A	2000m*2000m
p	1000 nodes
Simulation duration	1 hours
Flight parameter α	1, 1.9, 0.1
Pause parameter β	1.0
Average flight length	5-2000m
Pause time	10-60 seconds
hwv	1 meter/second
Location sample interval t_{ls}	1 second
(future location time) t_f	13 seconds
t_{vm}	15^{th} sec
t_{start}	16^{th} sec
vm and mn nodes range	200m
Range of sensor	20
Assumed datarate	100 kbps
req_{info}, $reply_{info}$, req_{sense} packet size	100 bytes
Each mn nodes sensor data size at each iteration	200 bytes

TABLE II
SIMULATION PARAMETERS

α	average velocity (m/s)
0.1	2.1
1.0	1.3
1.9	0.4

achieving required sensing coverage.

V. CONCLUSION

Human mobility plays an active role in improving the performance of mobile phone sensing applications, if their mobility characteristics are analysed and incorporated. This paper presents an human mobility based selective sensing framework called as HWSS for sensor data collection in opportunistic sensing networks. For the given network and applications parameters the proposed HWSS method show reduction in energy consumption and also achieves required spatial coverage. Our future work involves extending the proposed selective sensing to include multiple sensor data collection for ubiquitous mobile sensing applications. The future scope also involves analysing the computation and communication (varying geographical features and network link constrains) complexities involved in experimental implementation of proposed work.

Virtual sensing environment for care at home

Aristodemos Pnevmatikakis

44, Kifisias Ave., 15125 Marousi, Athens, Greece
Email: apne@ait.gr

***Abstract*—This paper presents a virtual home sensing environment, where different sensors are placed throughout the home and on the body of some care recipient. The life of the care recipient is then simulated and his/her activities trigger a wealth of measurements from the virtual sensors and the resulting metadata from processing those. The metadata are stored in a database, to be used for building activity recognition and condition reasoning systems in the context of home care.**

I. Introduction

Care at home for elderly people or long-term patients that can still live independently can be provided by monitoring and reasoning systems. These aim at providing both guidance and advice, but also a sense of independence and peace of mind for the care recipients and their families. To achieve this the systems turn each room of the home into a sensing environment. They also equip the body with permanent sensors, or urge the care recipient to periodically use some medical devices. The systems can also benefit from utilising measurements from multiple care recipients, all in their own environment. Only then can the systems reason about the context of the care recipient, gamify his/her everyday life and provide hints or respond to situations. Building such systems obviously requires a large installation base of the sensing infrastructure across multiple sites. This is very difficult to achieve at the early phase of a caring home system.

A shadow user is a simulation, driven by models for the home, the weather, the sensing environment and the behaviour of the user in it. The home model is fixed at initialisation time, the weather is obtained from an external service, and the sensing environment model comprises conditional probabilities of the measurements given the user state. Finally, the user behaviour model is described by state transition probabilities that vary based on four user driving forces, as discussed at the user state section.

This paper describes a virtual sensing environment that can be used to provide the necessary metadata for developing home-care systems. It is essentially a dual simulator, simulating on the one hand the life of the care recipient and on the other hand the sensor and signal processing entities that generate the metadata from the home and the body of the care recipient. The simulations are driven by models for the home, the weather, the sensing environment and the behaviour of the care recipient in it. The home and user models are fixed at initialisation time, the weather is obtained from an external service and the sensing environment model comprises conditional probabilities of the measurements given the user state. Finally, the user behaviour is determined by state transition probabilities that vary based on context parameters of the care recipient.

The resulting metadata are formatted into the same JSON messages utilised by the actual sensing system, e.g. as in the system described in [1] for the eWALL project [2]. They are then stored in non-SQL databases in a CouchDB database system, in a way that does not discriminate them at all from the actual ones.

The remainder of this paper is organised as follows: The home model is described in section II. The care recipient model is described in section III. Sensing the care recipient and metadata generation follow in Section IV. Section V discusses the implementation of the simulators and the results. Finally, in section VI the conclusions are drawn.

II. Home model

The home model contains the rooms their names and their insulation and window factors (α_{ins} and α_{win}) that are provided at initialisation. The outside space is also modelled as a room, to allow the care recipient exiting the home. Hence a home with four rooms is modelled by 5 possible spaces where activities can happen.

The environment in each room is affected by the outside environment (via the insulation and window factors) and the activities of the user. The outside environment is sampled every hour utilising the API of a weather service.

III. Care recipient model

The care recipient model comprises the state, the state transition probabilities, and four parameters enumerating the bodily and mental context of the care recipient. These are:

- Tiredness: As it increases towards 1, the user in increasing compelled to sleep. There is also a yearly decline factor introduced, which increases the base tiredness incurred by any activity over time.
- Hunger: As it increases towards 1, the user in increasing compelled to eat.
- Boredom: As it increases towards 1, the user in increasing compelled to do have entertainment or go for a walk.
- Toilet need: As it increases towards 1, the user in increasing compelled to visit the toilet.

Note that some actions are not even attempted if any of these context parameters is outside an allowed range.

A. Care recipient states

The care recipient state is characterised by the following parameters:

- Activity: sleeping, grooming, showering, eating, doing housework, entertaining, receiving visit, going out
- Room presence: where in the home he/she is. In part dictated by the activity
- Body posture: walking, standing (moving a little bit around the home), sitting, lying. In part dictated by the activity

The three components are connected, since the one influences the other: The activity fully determines the body posture and partly the room presence. E.g. the activity sleep determines fully the body posture (lying) and partly the room (bedroom or living room).

Overall the care recipient simulator supports 25 states, depicted in Fig. 1. Each state is described by room presence, body posture, certain activity and the amount tiredness, hunger, boredom and toilet need change after remaining for 10 sec in the state.

B. State transitions and their constraints

State transitions govern the way the simulated care recipient's life evolves. The transitions are described by transition probabilities that depend on the current state (the activity and the four context parameters of the care recipient), the time of day and the weather.

The allowed state transitions can also be seen in Fig. 1. Their probabilities have a base part, modified linearly by factors depending on tiredness, hunger, boredom and toilet need. The transitions are only allowed if all these four context parameters $c = [\text{tiredness, hunger, boredom, toilet need}]$ are within certain limits. For every transition from the i-th to the j-th state, the base probability is $p_b^{(i\to j)}$, the linear factors for context parameter c_n, $n = 1, ..., 4$, are $\alpha_n^{(i\to j)}$ and the corresponding allowed ranges are $D_n^{(i\to j)}$ then the transition probabilities are given by:

$$p^{(i\to j)} = \begin{cases} p_b^{(i\to j)} + \sum\limits_n \alpha_n^{(i\to j)} c_n & \text{if } c_n \in D_n^{(i\to j)} \\ 0 & \text{elsewhere} \end{cases} \quad (1)$$

The weather only modifies the probability of the user going out or returning home: Bad weather (cold, rain) tends to keep the care recipient indoors or hasten him/her back home. Certain time intervals result into a reduction of the probability of transition into sleeping, napping, going outdoors or receiving visits.

IV. Sensing and metadata

Sensing models describe the sensors and the perceptual components in the home. These are grouped per location and function, each group providing metadata in a database in the CouchDB. These models are detailed in the following subsections. They result to metadata being written in the respective CouchDB databases.

Note that there is another database being written, containing the state of the care recipient. This is not a result of sensing, but contain valuable metadata for evaluating the performance of systems that reason about the context of the care recipient, based on the sensed metadata.

A. Environmental sensing

The readings of the environmental sensors in each room depend on the outside environment and the activities of the care recipient. The outside environment affects temperature, humidity and luminance.

The steady-state room temperature T_{ss} is modelled at an ideal temperature of $T_{ideal} = 21$ degrees Celsius, pulled towards the outside temperature T_{out}:

$$T_{ss} = \alpha_{ins} T_{ideal} + (1 - \alpha_{ins})\, T_{out} \quad (2)$$

A unity α_{ins} value renders outside conditions irrelevant, while a value of zero equates the room conditions to the outside ones.

The new steady-state room temperature is calculated every hour when the new weather data arrive. Any resulting temperature change is not applied instantly at the rooms: instead the expected room temperature T_{room} at simulation instance n is a linear combination of the expected room temperature at the previous simulation instance $n-1$ and the steady-state one:

$$T_{room}(n) = \alpha_{mem} T_{room}(n-1) + (1 - \alpha_{mem})\, T_{ss} \quad (3)$$

where α_{mem} is a memory factor. Since the simulator updates the room conditions once every 10 sec, a value of $\alpha_{mem} = 0.99$ will result to the expected conditions being fully applied in the room after about 17 minutes.

The measured room temperature deviates from the expected by some additive white measurement noise of standard deviation of 0.2 degrees.

The humidity is similarly simulated. The ideal (comfortable) level is 55%. The measurement noise standard deviation is 1.

The luminance is determined by the cloud coverage percentage, the time of day and the window factor of the room. The window factor determines how much of the outside illumination enters the room. During the night, the steady-state outside illumination value ranges from 0 lux (full clouds) to 1 lux (no clouds) plus a Gaussian component or standard deviation 1 (that is not allowed to result to negative values). During the day, the steady-state value ranges from 10 lux (full clouds) to 1010 lux (no clouds) plus a Gaussian component or standard deviation 20. The measured luminance is updated based on the product of the steady-state one times the window factor, with the usual memory factor.

The environmental sensor readings that are affected by the care recipient activities are temperature, humidity, presence, luminance, gas concentration and door status.

When the care recipient is present in a room, the probability the PIR sensor gives a positive reading increases as the user activity level increases. The PIR of any room can be active, based on the following probabilities conditioned to the user state:

- 0.01% if the care recipient is not present

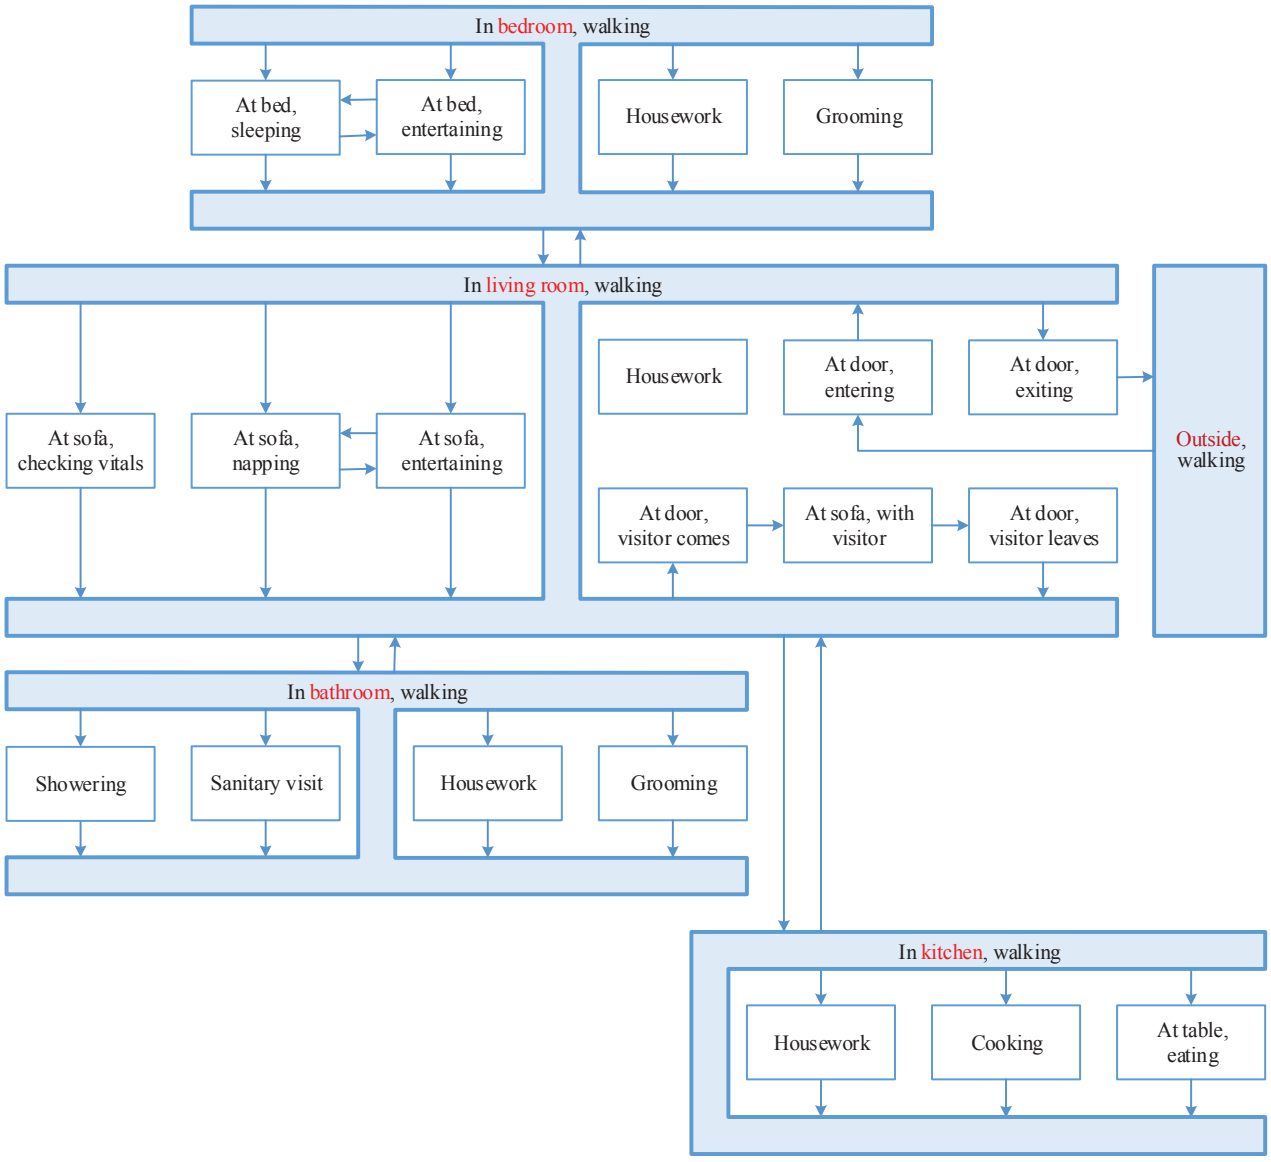

Fig. 1. The 25 states of the care recipient and their transitions. They are grouped into the five spaces (four rooms and outside) they belong to.

- 1% if the care recipient is lying
- 10% if the care recipient is sitting
- 50% if the care recipient is standing
- 90% is the care recipient is walking

If the care recipient is not lying down in a room that has luminance lower than 100 lux, then it is assumed that the lights are turned on, leading to an luminance of 100 lux plus a Gaussian component of standard deviation 2 lux.

If the care recipient is having a shower, then the humidity and temperature in the bathroom increase. The increase towards the target humidity of 90% is progressive, with a memory factor of 0.9. This factor is smaller than the one used for the change towards the environmental conditions, leading to faster humidity adaptation. The temperature target in the bathroom is 30 degrees. Similarly, if the care recipient is cooking, then the humidity and temperature in the kitchen increase. The target humidity is now 75% and the temperature target is 25 degrees.

Two gas concentrations are measured: CO and NG. If needed, LPG can be used instead of NG. Their values are simulated in parts per million (ppm), but are reported as integers between 0 and 10 in logarithmic scale. Zero corresponds to a reading at the minimum value the sensor can detect. The concentration of gases increases when the user is in the room. It increases ten times faster if the user is cooking. It decreases when the user is performing housework in the room, as the simulator assumes the windows are then open to air the room.

Only the status of the living room door (the main one towards outside) and the bathroom door is simulated, based on the activity of the user. The main door opens and closes

in two consecutive simulation steps when the care recipient or visitors enter or exit the home. The bathroom door closes when the shower or the toilet is used. The rest of the doors are always open.

B. Body sensing

Body sensing involves a wearable accelerometer. The simulation yields the number of steps and the Integral Modulus of Acceleration (IMA) depending on the care recipient state, specifically the body posture and the tiredness.

C. Visual sensing

Visual sensing employs a Kinect camera in the living room. A face tracking algorithm results to face tracks for the people present in the living room. Face analytics are employed to determine the expression, gender and age of the tracked faces. The simulation yields face tracks as follows:

- When the user is in the living room and being entertained, then it is very probable to have a single face track.
- When the user is in the living room but is walking or standing, then there is a small chance of having a face track.
- When the user has visits, then there are multiple face tracks.

The simulated expression changes between neutral, happiness and sadness based on the activity and the context parameters of the care recipient. The gender and age are fixed at initialisation for the care recipient, while for the visitors, they are randomly selected for each visit.

D. Resting surface sensing

Resting surfaces can be beds, sofas and different types of chairs. Resting surface sensing utilises a pressure sensor yielding binary values and an accelerometer yielding IMA values. A bed and a sofa are currently simulated. The simulation yields true for pressure with high probability when the user is sitting or lying on the surface, but also occasionally when the user is not. The simulated IMA is close to zero when the surface is unused, small when the care recipient is lying and moderate when sitting.

E. Socket sensing

The instantaneous power consumption, the overall energy consumption and the socket status are sensed for any necessary socket in the home. The two sockets where the living room and bedroom TVs are connected are simulated. The simulation always reports the sockets activated. Their power consumption ranges between a very small standby value when the care recipient is not entertaining, and the values specified by the particular TV models when the care recipient is entertaining. Forgetting the TV on is not supported.

F. Vital signs sensing

The vital signs being measured are the heart rate, the heart rate variation, the SPO2 and the systolic and diastolic blood pressures. The simulator assumes that all these values are made available in any vitals measuring session. All these vital parameters fluctuate around the nominal values in part randomly, and in part affected by the tiredness of the care recipient.

V. Discussion

This section discussed the implementation of the simulators for the care recipient status and the measurements conducted. It also presents results from long simulation runs.

A. Implementation

The virtual sensing system is written in Java 8. It comprises an initialisation JSON file that describes the care recipient parameters, the simulated interval, the virtual home and the states and their transitions.

The code is organised in four simulator packages and a database handling one:

- *simulator* contains the main and the graphical user interface classes
- *simulator.init* contains the classes for reading in the JSON initialisation file, obtaining the simulation parameters, the home structure in rooms, the body postures, the states and their transitions
- *simulator.models* contains the classes for the different types of sensing described in section IV
- *simulator.weather* contains the classes for obtaining the weather information
- *db* contains the class for managing metadata writing to the CouchDB

The simulators operate either in the past, in which case it runs 315 times faster than real-time (one day is simulated in 274 seconds), and in the present, in which case it waits for the next simulation epoch to actually arrive. This way both long periods of the past can be simulated in a matter of hours, and the implemented systems can be tested with the actual metadata rate in the present.

B. Results

The virtual sensing system currently is providing eight simulated care recipients, with metadata spanning 345 days (about 11.5 months, since Oct. 1st 2014). The average number of times each activity is exercised per day is shown in Table I for two care recipients: one whose base tiredness remains constant, and another who declines by 25% per year.

The average hours spent in three key activities (sleeping, walking and entertaining) and two activities that happen many times per day but at the end take up very little time (grooming and doing housework) are shown in Table II for the same two users.

The average distribution of the same activities in a day is shown in the histograms of Fig. 2. The care recipient always sleeps between 1:30 and 4:00 in the morning, with

TABLE I
AVERAGE NUMBER OF TIMES EACH ACTIVITY IS PERFORMED.

Activity	Daily avg., no decline	Daily avg., 25% decline
Toilet	3.60	3.20
Eating	4.64	4.08
Cooking	2.49	2.34
Showering	0.57	0.55
Sleeping	1.00	0.95
Napping	2.13	2.07
Outside	1.64	1.35
Visitors	0.45	0.52
Entertaining	3.76	3.54
Vitals	0.42	0.37
Grooming	5.51	4.69
Housework	4.49	3.62

TABLE II
AVERAGE TIME SPENT PER DAY DOING SOME ACTIVITIES.

Activity	Hours per day, no decline	Hours per day, 25% decline
Sleeping	11.11	12.72
Walking	2.86	2.40
Entertaining	5.95	4.80
Grooming	0.19	0.17
Housework	0.17	0.14

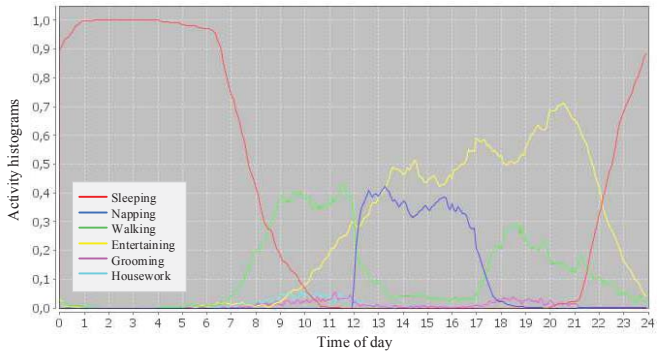

Fig. 2. Histograms of six activities showing the distribution across the day of sleeping, napping, walking, entertaining, grooming and doing housework.

the probability being above 90% from midnight to 6:40. The care recipient also rests in the afternoon, with a probability averaging 35% in the interval between 2:15 and 16:20. Comparing the results of Table I and Fig. 2, the care recipient has a single long sleeping session every night, while on average two short napping sessions every afternoon. The care recipient walks most in the morning (probability above 35% from 8:45 to noon) and again in the evening after the nap (probability above 20% from 17:45 to 20:00). Entertainment at the TV takes place mostly in the evening (probability increasingly above 40% from 13:10 to 22:00). Housework takes place in the morning, while grooming both in the morning and the evening.

Finally, the yearly decline factor is considered. The factor increases the base tiredness, forcing the care recipient to more relaxing activities. The effect of this in the average number of steps per month for the user with no decline and 25% yearly decline is examined. Both are shown in Fig. 3, together with the respective linear trends. The linear trend for the declining care recipient, projected to a complete year, is 24.5% in average steps, in line with the 25% yearly increase of the base tiredness. The linear trend for the non-declining care recipient, projected to a complete year, is 24.5% in average steps, consistent with the constant base tiredness.

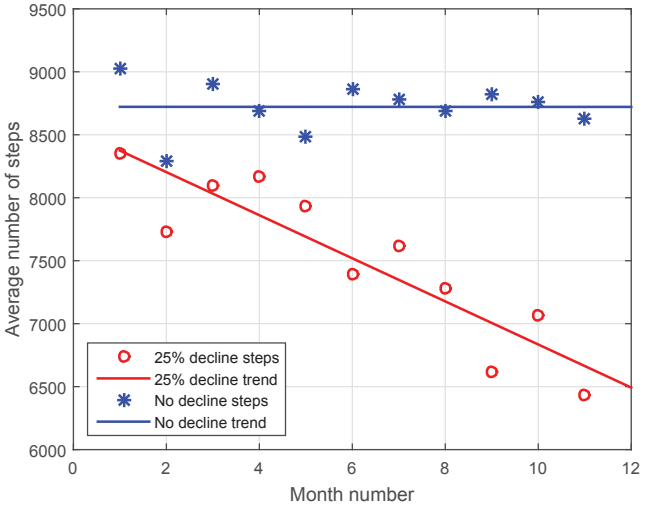

Fig. 3. Average number of steps per month for the declining and non-declining care recipients.

VI. CONCLUSION

A virtual home care environment has been implemented, comprising two simulators: one for the activities of the care recipient in the home and outside, and another for the measurements and the metadata from the systems observing the care recipients.

The virtual environment has been tested extensively, yielding plausible results, and is now in operation feeding eight home care systems with simulated metadata for about a year.

Running the virtual environments has allowed the testing of the reasoning systems of the eWALL project [2] against a wealth of situations, and the testing of the information displays both at home and at the care providers' end. Both tests would have been impossible without multiple full physical installations running for long times.

ACKNOWLEDGMENT

Part of this work has been carried out in the scope of the EC co-funded project eWALL (FP7-610658).

***Abstract*—Expression recognition is a contemporary research field determining human expressions based on image data using computer algorithms. It can be used in many applications including Ambient Assisted Living where a frequent expression recognition can be used to determine human's well being. In this work we propose an algorithm for expression recognition using images of human faces. The algorithm includes a feature extraction step by log-Gabor filters and a feature selection step using sparse approximation of the graph based embedding. The algorithm is tested using a popular database and provides competitive results when compared to other approaches.**

I. Introduction

The human face plays a significant role in social communications. It is the visual representation of the human personality, emotions and thoughts. The face we look at is a mix of both physical characteristics and expressions based on feelings and emotions. As such it can be a ground for capturing the humans' internal emotional state. Regular monitoring and estimating human expressions can be used to determine the well being of human's life on a daily basis. Potential application of such a system can be in the area of Ambient Assisted Living (AAL). This new initiative is trying to build the technological foundations for improving the life of elderly by providing home automation and general assistance intelligent algorithms. Estimating the emotional state of elderly can be an important component in such systems. Frequent bad mood can serve as an alarm to trigger further actions for stimulating more activities for mood improvement, e.g. stimulate more active social behavior, music listening etc.

The goal of facial expression recognition (FER) is to imitate the human visual system in the most similar way or in other words to enable the machine to have emotional intelligence. This is a very challenging task in the area of computer vision because it not only requires efficient image/video analysis techniques but also a well-suited feature vector used in the machine learning process. The general approach to FER consists of the following five steps [1]: Image acquisition, Preprocessing of image data, Feature Extraction, Selection and Classification.

With the boom of human-computer interactive systems there are many research papers proposing different approaches to achieve FER with different levels of success [2]. A big importance is the appropriate selection of local feature extraction algorithms [3]. In the work [4] the authors used a Gabor and log-Gabor filters for feature extraction and PCA for dimensionality reduction. Classification in this work is performed by Linear Discriminant Analysis achieving results of 85% recognition rate. In another work [5], the authors performed a detailed analysis on FER using local binary patterns (LBP) for feature extraction. They noted that LBP on average perform slightly better compared to Gabor filters as the method for feature extraction on high resolution images. On the contrary, Gabor filters perform comparably or better on low resolution images.

In another work [6], the authors built a FER system by employing local information and Gabor filters. They apply Gabor filtering in the area of interests around 28 key facial point located at places such as eyebrows, nose, chin etc. They used a K-Nearest Neighbors (KNN) classifier with preliminary PCA dimensionality reduction step. The achieved recognition rate is 80% on Cohn-Kanade database [7].

The authors in [8] presented a hybrid system based on sparse representation approach, using Gabor wavelet filter for feature extraction and support vector machine for classification. They introduced sparseness as means for approximating the test sample by the Gabor dictionary built from the training set. Then the approximation is used as input to SVM classifier for expression estimation. Their algorithm achieved 89% on JAFFE database.

In [9] the authors compared the recognition rate for three different feature selection schemes: MID-mRMR, MID-mRMR and a wrapper approach based on global optimization Genetic Algorithm. The features were extracted using log-Gabor filters and the classification is done with naive Bayesian classifier. The same authors proposed another approach for FER using log-Gabor filters and feature selection in [10]. The selected feature selection algorithm is based on mutual information and for classifier KNN is chosen. They achieved 75% recognition rate on Cohn-Kanade dataset. An up to date literature survey ot FER systems using feature extraction methods can be found in [11].

In this study, we propose a novel algorithm for FER based on feature extraction followed by feature selection. The log-Gabor filters are applied to extract the localized features from the image data. The gain of this step is alleviation of lightning variations as well as detailed multi-scale and multi-angle analysis. The feature selection step consists of graph a based feature selection algorithm. The feature selection method is

of filter type utilizing sparse combination of log-Gabor filters while preserving the intrinsic manifold on which the data resides approximated by a graph. Finally features are classified by SVM classifier. The remainder of this paper provides a detailed description of the proposed system, experiments and results. Section 2 describes the feature extraction algorithm. In section 3, the feature selection is described and in section 5 the experiments on the selected image database and results are provided. Section 6 concludes the paper.

II. Log-Gabor Feature Extraction

Facial expressions cause specific changes in the pattern of the face including change or introduction of wrinkles, change of geometry of different facial parts such as mouth and eyebrows. In order to capture such changes a multi scale analysis has to be carried out, localized at the areas of change. A common choice for obtaining localized frequency information of the pattern is to apply Gabor Filters. However, they have two major drawbacks: the maximum bandwidth is limited to approximately one octave and they are not optimal if one is seeking broad spectral information with maximal spatial localization. To overcome these disadvantages, an alternative to the Gabor Filter known as log-Gabor filters was proposed by Field in 1987 [12]. They have two important characteristics to note. The first one is that by definition log-Gabor filters do not have a DC component. In contrast, the Gabor filter cannot be constructed with arbitrarily wide bandwidth while maintaining a reasonably small DC component in the even-symmetric filter. The second one is that the transfer function for the log-Gabor filters has an extended tail at the high frequency end, providing sensitivity in the high frequencies. In the frequency domain the log-Gabor filters are represented by the following transfer function $H(f,\theta)$:

$$H(f,\theta) = H_f \times H_\theta \tag{1}$$

where H_f is the radial component, which controls the frequency band of the filter. H_θ is the angular one, which controls the spatial orientation of the filter. The transfer function $H(f,\theta)$ using polar coordinates can be written as:

$$H(f,\theta) = \left\{ \frac{-[ln(\frac{f}{f_0})]^2}{2[ln(\frac{\sigma_f}{f_0})]^2} \right\} \exp\left\{ \frac{-(\theta-\theta_0)}{2\sigma_\theta^2} \right\} \tag{2}$$

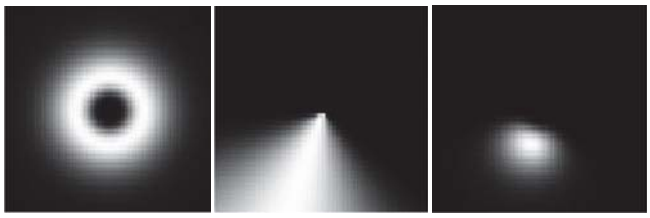
where f_0 is the center frequency of the filter and θ_0 the filter direction. The parameter σ_f defines the radial bandwidth B in octaves:

$$B = 2\sqrt{2/ln2} \times \|ln(\frac{\sigma_f}{f_0})\| \tag{3}$$

while the parameter σ_θ defines the angular bandwidth $\Delta\Omega$ in radians:

$$\Delta\Omega = 2\sigma_\theta\sqrt{2ln2} \tag{4}$$

Figure (1) depicts a visual representation of log-Gabor filters in the frequency domain. In 1a and 1b are presented the two components of the filter, the radial and the angular one respectively, for an arbitrary scale and orientation. In Fig. 1c the corresponding resultant filter combining both components is presented.



(a) Radial component (b) Anglular component (c) Resultant filter mask

Fig. 1. Log-Gabor filter in the frequency domain.

To extract the facial features we constructed Log-Gabor filters at several scales and orientations. The filtration process was carried out in the spectral domain, making it faster in comparison with the convolution in spatial domain. This process involves: 2D FFT image transformation into the spectral domain and multiplication of the resulted image by each log-Gabor transfer function. Each spectra is then transformed back to the spatial domain using 2D IFFT.

III. Feature Selection

The feature extraction process can increase the dimensionality of the data as it is with the current case of log-Gabor feature extraction. This will inevitable lead to the pronounced effect of the curse of dimensionality as well as increased computational load. For example, if the input face is of size 100×100 pixels and the selected filters scales are 5 and 4 orientations then the resultant dimensionality is $5 \times 4 \times 100 \times 100$ which is a dramatic increase of dimensionality, especially when the dataset is of size smaller than 1000 samples. To avoid this dimensionality explosion two approaches are usually used. The first one is of dimensionality reduction in which a linear or non-linear combination of features is searched. The second one is feature selection where only a small subset of the most representative features is selected.

In this work we utilize a method for feature selection based on graph embedding. The data adjacency graph is a discrete version and encodes the intrinsic data relations [13]. The data adjacency graph is represented in the form of a matrix where each coefficient is larger than zero if every two data points are related in some way, otherwise is zero. Let this matrix be $\mathbf{W}$ where each element W_{ij} encodes the data relation between points i and j. Depending on the task at hand different relations can be selected. Usually, in the supervised case an edge is placed if a couple of data points belongs to the same class. In the unsupervised case the similarity is calculated by appropriate function.

In our work we use two different ways for building the adjacency matrix. The first one is based on heat kernel similarity and every coefficient is calculated by:

$$W_{ij} = \begin{cases} \exp(-\dfrac{\|\mathbf{x}_i - \mathbf{x}_j\|}{\sigma}),\ \mathbf{x}_i, \mathbf{x}_j\ in\ same\ class \\ 0,\ otherwise \end{cases} \tag{5}$$

Given $\mathbf{W}$, let $\mathbf{D}$ is such that $Djj = \sum_i = W_{ij}$. Then, the matrix $\mathbf{L} = \mathbf{D} - \mathbf{W}$ is called the graph Laplacian and is a discrete analog to the Laplace-Beltrami operator. It can be proven [14] that the eigenvectors of this operator provide optimal embedding, preserving the adjacency of the data points in the embedding space. Hence, the eigenvectors of $\mathbf{L}$:

$$\mathbf{Lv} = \lambda \mathbf{Dv} \tag{6}$$

will provide optimal embedding, preserving the geometric structure encoded by $\mathbf{W}$. The matrix $\mathbf{V} = [\mathbf{v_1}, \mathbf{v_2}, ..., \mathbf{v_M}]$ with M eigenvectors corresponding to the smallest M eigenvalues is the optimal data embedding which preserves the geometrical structure. Clever observation that the eigenvectors $\mathbf{V}$ can be used in regression framework for learning mapping functions is developed in [15]. This framework can be used in the linear as well as in the kernel modes. Moreover different regularization schemes can be used. Since the feature selection is a sparse problem, the l_1 regularization is appropriate in our case. The regression problem in the sparse case is formalized as:

$$\min_{\mathbf{b}_m} \|\mathbf{v}_m - \mathbf{F}\mathbf{b}_m\| - \beta \|\mathbf{b}_m\|_1 \tag{7}$$

where $m = [1, 2, ..., M]$ and $\mathbf{F}$ are the log-Gabor features. The l_1 norm will zero out most of the coefficients of $\mathbf{b}_m$ and will provide means for feature selection.

We use the following criteria for feature selection [16]:

$$MCFS(j) = \max_m |b_{mj}| \tag{8}$$

where b_{kj} is the $j-th$ element of the $m-th$ vector. In other words MCFS selects the biggest weight per vector component across all vectors $\mathbf{b}_m$. The result of this operation is a vector of size M and the next step is to arrange the vector components in ascending order. Finally the features are selected by selecting the first d components.

IV. Experimental Results

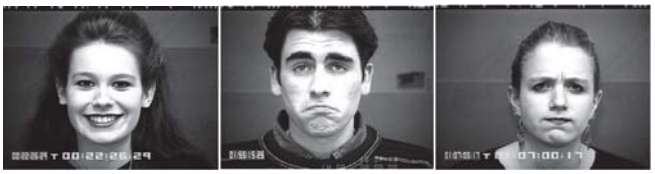
A. Facial Expressions Dataset

For the experimental setup in this study we used Cohn-Kanade Extended Facial Expression Database (CK+) [7]. This database is intended for development, evaluation and comparison of algorithms for expression recognition. It contains facial photos of 123 persons in 593 image sequences. For a subset of 118 persons there is a corresponding annotation file (i.e. the ground truth data) that describes each persons expression. The following seven expressions are taken into account: anger, contempt, disgust, fear, happy, sad and surprise. The distribution of the number of images per expression is presented in Table I.

TABLE I
Number of images per class in Cohn-Kanade Extended [7]

Anger	Contempt	Disgust	Fear	Happy	Sad	Surprise
45	18	59	25	69	28	83

A sample from the database is presented in Fig. 2.



(a) Happy (b) Sad (c) Anger

Fig. 2. Log-Gabor filter in the frequency domain.

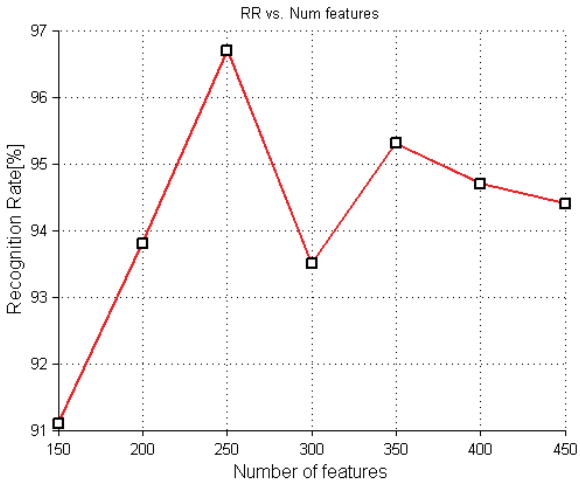


Fig. 3. Recognition rate as function of number of features.

B. Experimental setup and results

For the classifier we selected Support Vector Machines with radial basis kernel function, implemented in LIBSVM [17] and 10 fold cross validation. The value of the parameter σ of the weight matrix similarity function was experimentally chosen to be 0.1. The selected number of scales is 3 and the orientations 5. The images were resized to 60×50 pixels resulting in a feature vector with 45000 elements. The number of selected features was also selected experimentally to 250. In Fig. 3 is presented the recognition rate in % as function of the number of features. It can be observed that the peak is at around 250 features and the recognition rate is 96.7%.

The results are compared with the ones obtained in [6], [5] and [10] as shown in Table II.

TABLE II
Comparison of different algorithms

Algorithm	Recognition Rate[%]
Ou et al. [6]	80
Shan et al. [5]	92.6
Proposed	96.7

An important observation is that the Cohn-Kanade dataset is rather small and thus prone to bias when used in cross-validation setting. Thus, to validate our results we conducted tests in person independent mode (leave-one-person-out) where the images of one person are not used for training,

but only for testing. The recognition rate we achieved is 87% and is higher than the results presented in [9] where person independent tests were also performed.

V. Conclusion

The experiments carried out in this paper prove that graph based feature selection can deliver very good results even when used in filter mode. In total 250 out of 45000 features were selected which is 180 times reduction of dimensionality. The algorithm provides competitive results in cross-validation and person independent test setting when compared to others. As future work, investigation will be carried out to use the feature selection in wrapper or embedded mode. Also different adjacency matrix will be tested.

***Abstract*—Ambient Assisted Living (AAL) systems aim to support independent living and improve the everyday quality of life of both healthy elderly and disabled people. The Internet of Things (IoT) which can really improve the performance and the efficiency of AAL applications that are built upon Wireless Sensor Networks (WSNs). The AAL applications that include getting data for the patients, monitoring their vital signs and identifying abnormal situations that need medical attention is assumed to be critical applications that have very strict Quality of Service, security and trust requirements. Regarding the latter, it is expected that the devices that are included in AAL systems are trusted and provide reliable measurements. In this work, we propose a model for calculating the trustworthiness of IoT devices and the adaptation of the model for the computation of trusted routing paths in an IoT network. For the trust model we use both statistics for the behaviour of the devices, as well as for the quality of the links in the network, in order to be able to identify the malicious or malfunctioning nodes and to increase the packet delivery ratio, thus increasing the reliability of the overall system.**

I. Introduction

The Internet of Things (IoT) aims to interconnect efficiently large numbers of physical and digital objects, e.g. cars, doors, rooms, mobile phones, etc. The goal is to create a global network infrastructure where all objects will be able to “talk" to each other. All real world objects are interconnected either directly (e.g. by attaching to them ICT devices that monitor or control them) or indirectly (by using remote devices that monitor their attributes) without any human intervention providing advanced applications to the users. These IoT-based applications span in a plethora of sectors, i.e. smart agriculture, smart food, smart buildings, smart cities, etc. [1]. Home automation is considered a broad research area for new IoT-based applications that have a direct impact on the everyday life of human users. As it has been identified lately, security, privacy and trust are main obstacles for the general acceptance of the IoT applications by the general public [2], [3].

Intelligent Building Management Systems (IBMS) can be considered as the basis for providing critical home automation applications, i.e. for smart health, monitoring the health status of the inhabitants. This can be considered as part of Ambient Assisted Living (AAL) system, which aims to provide an ecosystem for medical applications supporting user-dependent services for the disabled and the elderly [6]. The main goal of AAL systems is to allow the elderly or disabled people to live autonomously, automating most of their everyday activities and increasing the safety in their everyday lives. AAL applications include among others monitoring the vital signs of the people, tracking of their movement (mainly indoors), identifying falls and calling for assistance when health-related alarms are raised. The demographic change that results in the increase of life expectancy and the decrease in the birth rates raises the need for such applications [4].

The success of AAL applications depends on the level of trust that the users have on the system that provides these applications. It is reasonable to assume that if a user does not trust the system he will not use it. The level of trust can be affected by many factors, i.e. by personal experience that stems from previous engagement with the system, by proofs of the performance of the system or by recommendations from other known users. Assuming that there are many devices feeding data to the AAL applications, these devices have to be reliable and trusted to ensure that decisions taken by the system are not affected by malicious or malfunctioning devices. Previous works have focused on trust management in AAL applications in a very generic point of view ([5] and the references therein). Here we focus on the trust from the networking point of view, introducing trust as a routing metric in multi-hop IoT deployments, in order to compute routing paths that are formed by trusted devices when there is a need to provide sensitive AAL applications. The goal is to create a trusted routing a scheme that considers the following: (i) behavioral statistics of sensors reported by their one-hop neighbors, (ii) link quality statistics, and (iii) a fusion scheme based on the Dempster Shafer theory of evidence.

The rest of this paper is structured as follows: in section II we provide a brief overview of the state of the art. In section III, we discuss the system and trust model. In section IV we describe the trusted routing mechanism. In section V we provide the simulation setup and the performance evaluation, while in section VI we conclude the work.

II. Related Work

Node reputation has been introduced as a trust mechanism in several publications that provide classification schemes and information about how to evaluate reputation and trust, but

they are quite focused only on users' ratings. Probabilistic theory [8], Hidden Markov Model [9], ontologies [10] semantics [11] and fuzzy models have been employed in reputation calculations and modelling. Gligor and Wing [12] present a theory of trust in networks of humans and computers that consists of elements of computational trust and behavioural trust. There are two types of trust [13]: (1) social trust that is a subjective metric based on friendship, honesty, social interactions, social reputation and history, and (2) QoS trust that is a more objective metric based on QoS measurements.

Trust management has been used as an easy and efficient approach to mitigate a wide number of attacks in opportunistic routing [15] in wireless sensor networks. Nodes create trust relationships based on the expectation that their neighbours will cooperate on particular tasks (e.g. packet forwarding) and decide on routing paths based on them. In [14] a trust management protocol is applied in geographical routing for WSNs that is able to avoid attackers by routing through benevolent neighbours. In [16] the authors design a trust-aware routing framework that can cope with various harmful attacks with no time synchronization or geographic information, while [17] describes a routing scheme that expresses routing reputation by combining link quality and node behaviour. Finally, in [18] a hierarchical (social and QoS) trust management scheme for heterogeneous sensor networks is introduced.

III. System Model

A. Network Model

We follow the approach of Virtual Sensor Networks (VSNs). According to [19] a Virtual Sensor Network is formed by an appropriate subset of sensor nodes of a standard Wireless Sensor Network (WSN). This subset collaborates in order to provide a specific service as requested by an application. A virtual sensor network is basically formed by interconnecting logically (and not always physically) collaborative sensor nodes. An Overlay Sensor Network is a network that is built on top of a standard Wireless Sensor Network in a similar way that the Internet was built on top of a telephone network. The overlay network creates a virtual topology comprising nodes that are connected with virtual links that correspond to paths of the underlying network.

We model the network as an overlay bi-directed graph G(V,E) where V is the set of nodes (smart objects), including a single sink node (normally the Gateway), and E is the set of edges representing wireless links between nodes, as depicted in Figure 1. Of course IoT networks are normally in larger scale, but we can use clustering (as in [20] to divide the network into smaller parts. The sink node is normally not a constrained device, meaning that it is reasonably powerful with increased capabilities with regards to processing, memory and energy. We assume that each node of the network has a limited communication range, thus can directly communicate only with the nodes that reside inside his range, which we call them his "neighbours". Communication with the sink is possible in a multi-hop fashion with each node following a path calculated through a respective algorithm at the sink.

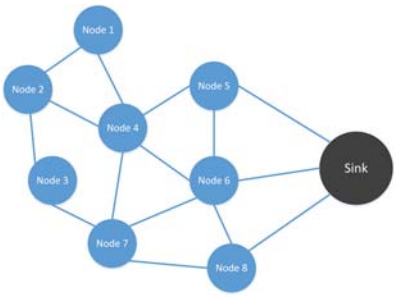

Fig. 1: Network model.

B. Trust Modeling

In this work the trust model is based on statistics that relate with the behaviour of each node in terms of dropping packets or modifying them and on the statistics of the link quality between the nodes, since the latter affects also the possibility of correct reception of the measurements at the sink.

1) Behavioural Statistics: The first part of the trust model is related with creating a metric for considering the behaviour of the nodes that are parts of the network of the devices that provide the AAL applications. We assume that there may be some devices that can be either malfunctioning (i.e. due to hardware or software failures) or tampered with by malicious third parties. The trust model is built on the evaluation of trust degree values based on the observed behaviour of a network node by its neighbours. Each node observes and records a neighbour's abnormal behaviour each time there is an interaction between them, while it also keeps track of the total amount of incoming packets. For the sake of simplicity and to keep the communication and signalling overhead low, two statistics that capture the forwarding behaviour of an node are used: (i) packet drop rate (PDR) and (ii) packet modification rate (PMR) defined as follows:

$$PDR = \frac{\#\text{of dropped packets}}{\text{total}\,\#\text{of received packets}} \tag{1}$$

$$PMR = \frac{\#\text{of modified packets}}{\text{total}\,\#\text{of forwarded packets}} \tag{2}$$

We assume that there is a sender node i and a receiver neighbour j. Each time i sends a packet to j, it enters promiscuous mode to overhear the forwarding behaviour of j and it updates accordingly the values of $PDR_{i,j}$ and $PMR_{i,j}$. Then, the aggregate MisBehaviour Rate (MBR) of node j as perceived by a node i is calculated as:

$$MBR_{i,j} = w \times PDR_{i,j} + (1-w) \times PMR_{i,j} \tag{3}$$

where $w \in [0,1]$ is a user-defined weight controlling the balance between the behavioural statistics.

2) Link Quality Statistics: Using only the behavioural statistics for evaluating the trustworthiness of a node can be indeed useful to isolate malicious nodes in the network. However, to improve the performance and allow the metric to be used as a routing metric we have to also take into consideration a link quality metric for the optimal path calculation of the routing algorithm. Here, we use the estimated transmission count (ETX) metric [21] to quantify the reliability of the link

between any two nodes within the network. ETX is one of the most widely used routing metrics due to its simplicity and computational efficiency. The ETX calculated for node i by node j is defined as:

$$ETX_{i,j} = \frac{1}{f_{i,j} \cdot r_{i,j}} \quad (4)$$

where $f_{i,j}$ is the forward delivery ratio, i.e. the measured probability that a packet sent from node i is received by node j, and $r_{i,j}$ is the reverse delivery ratio, i.e. the measured probability that the acknowledgement packet from node j will be received by node i. Thus, ETX expresses the average number of transmissions needed for a packet to successfully reach its destination in cases when there are transmission failures due to degradation of link quality.

3) Behavioural Trust Fusion: The calculation of the MBRs for each one of the nodes in the network is assumed to be a crucial step in the proposed routing scheme. For this calculation the observations and the recordings of the statistics by the interacting neighbours are utilized. However, since for this calculation we can't be sure that the observations and the reported values are accurate and reliable, we need an appropriate combination technique to fuse the neighbour views. In our framework, each node builds a local view of the neighbours' behaviour from its own observations. As a result, the reported views may be biased or intentionally wrong, leading to the existence of uncertainty. Therefore, we propose the use of Dempster-Shafer (DS) theory of evidence [22], [23] as a fusion technique. DS is a mathematical framework able to handle uncertainty of the complete probabilistic model describing the system under consideration. Essential terminology related to DS and used throughout this section is presented below to ease the reader to understand our contribution:

- Frame of discernment Θ, which is the set of all possible mutually exclusive and complete states of a system. Here, the frame of discernment is defined as Θ = trust, no-trust.
- Mass function (probability assignment) m. $m : 2^{\theta} \rightarrow [0,1]$ is a mass function if $m(\emptyset) = 0$ and $\sum_{A \subset \Theta} m(A) = 1$. A is any proposition that is a subset of Θ.
- Belief function, which measures the belief of a proposition A and computes the sum of all the nonempty subsets of A. It is given by the formula $Bel(A) = \sum_{B \subseteq A} m(B)$, where B are the nonempty subsets that compose A. Here, since the belief on a node's trust depends only on the MBR value, the belief and the mass functions are equivalent.
- Focal elements of a frame of discernment Θ, which are comprised of all hypotheses for which the observers can provide evidence. In our case, where $\Theta = \{trust, no-trust\}$, the corresponding focal elements form the set $[trust, no-trust, trust, no-trust]$, where the last element shows the uncertainty for the trustworthiness of one node.

Individual beliefs on each node's trust as reported by each of its interacting neighbours can be combined into a single belief by applying Dempster's rule of combination:

$$m_1(A) \oplus m_2(A) = \frac{\sum_{B \cap C = A} m_1(B) m_2(C)}{1 - \sum_{B \cap C = \emptyset} m_1(B) m_2(C)}$$

Belief \ MBR	$MBR < h(1-r)$	$MBR > h(1+r)$	$h(1-r) \le MBR \le h(1+r)$
b^T	$c+\lvert h-MBR \rvert / h$	$(1-b_r)/2$	1/3
b^U	$(1-b_r)/2$	$c+\lvert h-MBR \rvert / h$	1/3
b^{TU}	$(1-b_r)/2$	$(1-b_r)/2$	1/3

Fig. 2: Belief Computation

In cases where there are in total N neighbours reporting individual beliefs for a specific node, the belief functions can be combined sequentially in any order (due to the associative property of DS), as expressed by the following formula:

$$m_{1\ldots K}(A) = \bigoplus_{k=1}^{K} m_k(A) \quad (5)$$

Each neighbour produces a single belief for each focal element (b^T: belief that a node is trusted, b^U: belief that a node is untrusted, b^{TU}: belief expressing ambiguity) according to the table in Figure 2.

The uncertainty area lies between $h(1-r)$ and $h(1+r)$, where$h$ is a user-defined threshold (since every user has a different perception of trust), $0 < r < 1$ is a user-defined scalar controlling the width of the uncertainty area and c is a scalar controlling how fast trust/distrust belief increases. By combining the believes of trust reported by each node for their neighbours we calculate the trust degree of a node j, denoted as b_j^{CT} , by using Equation 5. We have to note here that the belief and the mass functions are equivalent, since node trust is characterized only by a single basic event (MBR).

IV. Trusted Routing with Link Quality

Considering both the trust degree b_j^{CT} and the link quality as quantized by $ETX_{i,j}$ a combined routing metric on a route r from a node to the sink can be defined as

$$RM_r = \sum_{i,j \in r} ETX_{i,j} \left(1 - b_j^{CT}\right) \quad (6)$$

We find the shortest path from each node to the sink using the classic algorithm of Dijkstra [24]. The "shortest path" in this context shows a path that has both a low number of retransmissions at the links and comprises of nodes that have a high trust degree. In the following, the steps of the proposed trust-based routing scheme are described.

a) Initialization: Each node measures the ETX metric by broadcasting a probe packet periodically with a fixed time interval. Additionally, it sends a packet containing the count of probe packets from its neighbours, so that all nodes can calculate the loss of probe packets on both directions of a link. Subsequently, the calculated ETX values are flooded to the sink. At this time no behavioural statistics are available and all nodes are assigned a trust degree of 0.5 (neither trusted nor untrusted). Optimal paths are computed using Dijkstra's algorithm and are broadcasted to the network.

b) Trust belief update: The behaviour of malicious (or malfunctioning) nodes is possible to change over time; as a result, it is necessary to update periodically the trust values

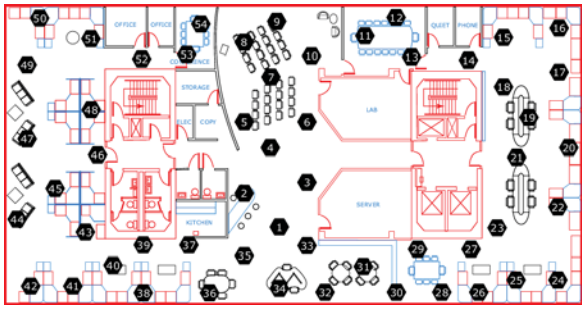

Fig. 3: Intel Berkeley lab sensor network topology.

assigned to each node. While a node interacts with its neighbours, it observes and records their behaviour and recalculates accordingly the behavioural statistics, the total misbehaviour rate and, finally, the trust belief. After a predefined trust update interval Δt we have:

$$b'^{T}_{i,j}(t+\Delta t) = \theta \times b^{T}_{i,j}(t) + (1-\theta) \times b^{T}_{i,j}(t+\Delta t)$$

where $\theta \in [0,1]$ is a weighting factor that balances current and previous estimation of misbehaviour rate. We choose to use a different weighting factor depending on whether the MBR has increased or decreased, as follows:

$$\theta = \begin{cases} \theta_1, & \text{if } b^{T}_{i,j}(t+\Delta t) > b^{T}_{i,j}(t) \\ \theta_2, & \text{if } b^{T}_{i,j}(t+\Delta t) \leq b^{T}_{i,j}(t) \end{cases}$$

with $\theta_1 > \theta_2$.

As a result, trust degree decreases quickly in case of misbehaviour but increases slowly in case of improved behaviour.

c) Routes update: After updating the trust degree, each node calculates the beliefs for the neighbours based on the Table in Figure 2. New beliefs are sent to the sink where they are fused based on Dempster-Shafer rule of combination, so that a combined trust belief b_j^{CT} and distrust belief b_j^{CU} is assigned to each node j. We use a threshold B_{mal} to detect malicious or misbehaving nodes, in other words if $b_j^{CU} > B_{mal}$, then node j is considered untrusted and it is omitted from the routing paths. Afterwards, the optimal routing paths are found through Dijkstra's algorithm, by considering the combined metric defined in Equation 5.

V. Performance Evaluation

In order to evaluate the proposed scheme we assume the indoor sensor network of Figure 3 (http://db.csail.mit.edu/labdata/labdata.html), which corresponds to a deployment of 54 Mica2Dot sensors at Intel Berkeley lab employed with weather boards to monitor low frequency phenomena (humidity, temperature, light and voltage). Both topology information (nodes' coordinates) and bi-directional link quality (probability of successful transmission that can be used to easily compute ETX values) are available online .

We choose randomly a node as the sink and we conduct simulations for data aggregation rounds. Trust belief update interval is set to 20 rounds, while we choose $c = 0.1$, $h = 0.5$, $r = 0.05$ and $w = 0.5$. In order to account for some variance of wireless channel characteristics, in each round we vary

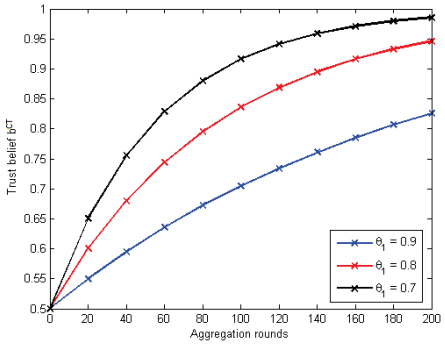

Fig. 4: Trust belief of normal node.

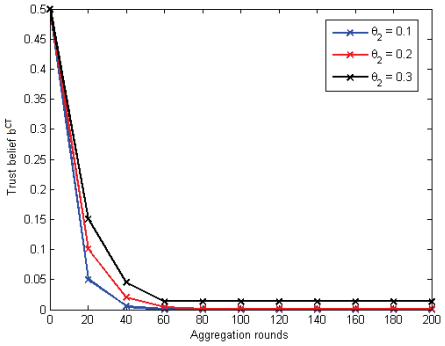

Fig. 5: Trust belief of malicious node.

randomly the ETX of all links in [90%, 110%] of their nominal values. Figure 4 and Figure 5 show the combined trust belief for a normal and a malicious node, respectively, and for various values of weights θ_1 and θ_2 . Obviously, an increase of θ_1 reduces the rate of trust belief increase, applying more significance on history data. Similarly, an increase of θ_2 causes trust belief to decrease slower. Furthermore, we can see that the disbelief for a node (who has low trustworthiness) is calculated very quickly, which means that in only a few rounds we can identify which nodes are untrusted and avoid them in future routing decisions. Generally, by choosing the appropriate values for θ_1 and θ_2 we can assure that our scheme becomes more sensitive to malicious actions, enabling the quick omission of the malicious nodes from the routing paths.

Next, we proceed by evaluating our scheme by means of

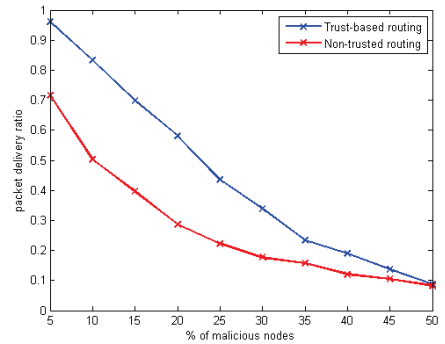

Fig. 6: Packet delivery ratio (highly malicious behaviour).

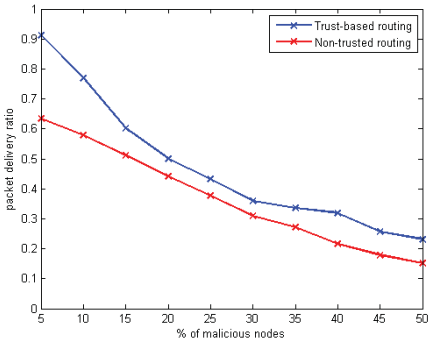

Fig. 7: Packet delivery ratio (low malicious behaviour).

packet delivery ratio at the sink. We assume two scenarios, namely highly malicious behaviour and low malicious behaviour. In first case, malicious nodes exhibit PDR and PMR with values in [0.8,1] while in second case the values vary in [0.3,0.5]. For each scenario we execute 20 Monte Carlo runs each consisting of 2000 data aggregation rounds. The proposed trust-based routing scheme is compared against a simple routing scheme with no trust management mechanism. Mean packet delivery ratio (averaged over all runs) vs percentage of malicious nodes for highly malicious behaviour and low malicious behaviour is depicted in Figure 6 and Figure 7, respectively. Observe that in both cases the trust-based scheme outperforms the simple scheme, with the difference being more profound for small number of malicious nodes and highly malicious behaviour. For example, in case of 5-20% of highly malicious nodes there is an increase of more than 30% in packet delivery ratio. Normally, as the number of malicious nodes increases the packet delivery ratio for both routing schemes is almost equal.

VI. Conclusion

In this paper we presented a trust model for evaluating the trustworthiness of nodes that are providing AAL applications. The trust scheme is based on both node behaviour (for identifying malicious or misbehaving nodes) and link quality statistics (to identify lossy links) in order to ensure that the resulting routing paths will include only trusted nodes with high reliable links so that no information will be lost or tampered with. Since AAL applications are sensitive applications that affect the quality of life and the well-being of elderly or disabled people, the measurements gathered from the devices (i.e. vitals from wearables, fall detection) are critical and have to be sent to the AAL system with the highest protection. The scheme proposed in this paper, as shown in the evaluation section, can quickly identify malicious or misbehaving nodes and can isolate them from the network routes. The percentage of delivered packets can also be significantly improved even in the case of many malicious/malfunctioning nodes in the network. Future steps include the extension of the trust model to include more trust metrics for addressing more attacks and a more formal expression of the trusted routing metric.

***Abstract* - One of the main concerns in the era of aging population is how to enable senior citizens to live independently. In order to solve this problem, systems for independent living of senior citizens are being developed. In process of delivering these systems to end users, evaluation plays a crucial role. In this paper evaluation and testing of the European project FP7 eWALL for Active Long Living system is presented. Different technologies that have been used in system development are listed. The emphasis is put on evaluation methodologies and challenges that were encountered during system evaluation. In addition, possibilities in improving system evaluation have been listed.**

Keywords-component; Cloud, network architecture, end to end testing

I. INTRODUCTION

The verification and the validation processes form part of the larger process of software engineering. Thus, from a process viewpoint, software testing, as a part of verification and validation can be viewed as being included within software engineering, which, in turn, is a part of systems engineering. In fact, the systems engineering, the software engineering and the verification and validation processes are all covered by corresponding standards (ISO 15288:2015 "Systems and software engineering - System life cycle processes", ISO 12207:2008 "Systems and software engineering - Software life cycle processes" and IEEE 1012 "Standard for software verification and validation" respectively). Each of these standards contains requirements relevant to the software tester. Both ISO 15288 and ISO 12207 include processes for verification and validation, and although many software developers and testers ignore the systems aspect of their work, it is impossible to deny the relevance of ISO 12207, the software life cycle processes standard. The software maintenance life cycle process begins with process implementation, where planning for maintenance is performed and ends with the retirement of the software product. It includes modification of code and documentation due to a problem or as a need for improvement. The objective of the maintenance process is to modify an existing software product while preserving its integrity. According to ISO/IEC 14764:2006 "Software Engineering - Software Life Cycle Processes - Maintenance" [1] Figure 1 shows standard steps should be performed.

a) Trace the modification request-MR/problem report-PR from requirements, to design, to code;
b) Verify testability of the code;
c) Verify conformance with coding standards;
d) Verify that only necessary software components were modified;
e) Verify that the new software components were integrated properly;
f) Check documentation to ensure that it was updated;
g) Configuration management-CM personnel build software items for testing;
h) Perform testing by an independent test organization;
i) Perform system tests on a fully integrated system;
j) Develop test report

Figure 1: Steps of maintenance process

II. EWALL SYSTEM ARCHITECTURE

According to the ISO/IEC/IEEE 42010 "Systems and software engineering - Architecture description", an international standard for architecture descriptions of systems and software, the architecture is defined as “fundamental concepts or properties of a system in its environment embodied in its elements, relationships, and in the principles of its design and evolution”. The eWALL project considers system architecture as “the conceptual model that defines the structure, behavior and more views of a system” [1].

The chosen description methodology for specification of eWALL system architecture is founded on ARCADE framework [2]; an open architectural description framework based on the IEEE 1471-2000 "Recommended Practice for

Architecture Description of Software-Intensive Systems" standards. Furthermore, as it is important to show how different selected hardware components (sensors, actuators, user interaction devices, servers) will interact with developed software components to form a unique eWALL system. Figure 2 shows the holistic Service Oriented Architecture of eWALL system. The OMG Systems Modeling Language (OMG SysML™) has been selected as the main modeling language for eWALL system architecture definition. SysML is a general-purpose modeling language for systems engineering applications and it is defined as an extension of a subset of the Unified Modeling Language (UML). Produced preliminary eWALL SysML model helped share understanding of system design, and will further assist in managing complex eWALL system development. Cloud deployment models the eWALL cloud environment infrastructure (eWALL IaaS) as an Openstack-based private cloud, which has been set up on dedicated hardware infrastructure. Figure 3 shows parallel environments in the eWALL cloud. The private cloud allows configuring and using a set of parallel environments, each one enabling a fully functional server-side eWALL system, to be used within the eWALL Consortium for a specific phase of the application management lifecycle. Four parallel environments have been set up, dedicated respectively to: development activities, integration testing activities, end-to-end testing and validation activities and production-level solution hosting. In addition to them, an application lifecycle management environment was created, which orchestrates the software artifacts management and deployment towards the parallel environments and executes the automated testing tasks.

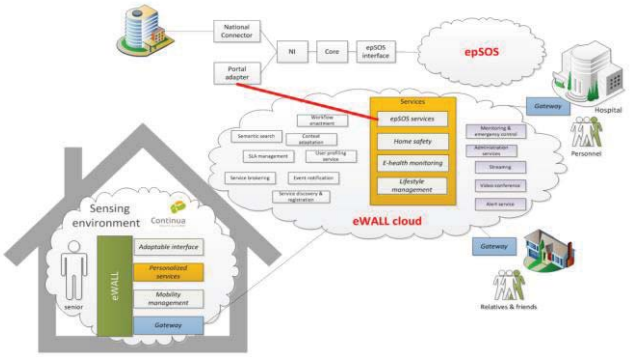

Figure 2: The holistic Service Oriented Architecture of eWALL

Within each of the parallel environments, the same set of components constituting the eWALL central system are deployed and executed. Figure 3 depicts the deployment model for one of such parallel environments (namely the integration test environment). The other ones follow exactly the same deployment pattern. The only difference between the parallel environments lies in the computational resources allocated for them (production and validation environments are assigned more resources, as they are expected to support higher usage loads). In the sample environment of Figure 4, the eWALL components are deployed on four virtual servers. One virtual server is dedicated to hosting applications and service bricks. The communication with the external world is based on http/REST. The second server is dedicated to caching. Cache server software (memcached) is installed on the server, and is accessed by the other components of the system to store in the cache or to get from the cache sets of data. This allows for optimization of network usage and response time, which directly affects the QoS of the platform. The third server is dedicated to the Horizontal services and Cloud middleware services of the eWALL platform. Since such components are responsible for data exchange with both local and remote components, they also can communicate with the external world via http/REST. The fourth server is dedicated to data storage. Such machine hosts a MongoDB server, which is accessed by the data management component of the Cloud middleware services, to store or provide data to the eWALL components.

Since the components are loosely coupled by design (they all communicate via stateless, web service protocol) the deployment model described above can be easily changed and adapted to different requirements. Additional virtual servers can be added to the deployment scenario and most of the components can be distributed on them. As an example, based on the number of applications and service bricks in the platform at a certain moment, it might be preferable to separate such components on different servers seamlessly (or, as an alternative, deploy additional ones on new servers).

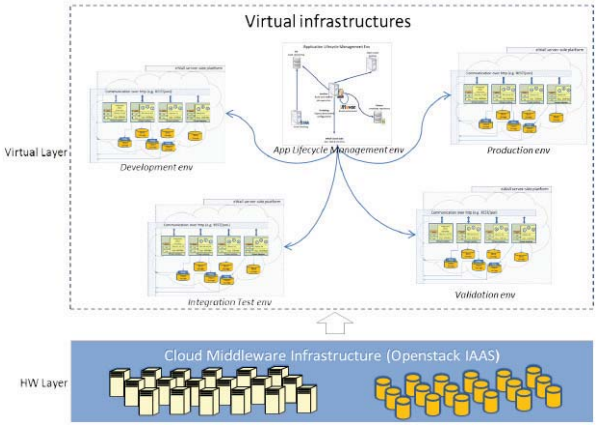

Figure 3: Parallel environments in the eWALL cloud

Within each of the parallel environments, the same set of components constituting the eWALL central system are deployed and executed. Figure 3 depicts the deployment model for one of such parallel environments (namely the integration test environment). The other ones follow exactly the same deployment pattern. The only difference between the parallel environments lies in the computational resources allocated for them (production and validation environments are assigned more resources, as they are expected to support higher usage loads). In the sample environment of Figure 4, the eWALL components are deployed on four virtual servers. One virtual server is dedicated to hosting applications and service bricks. Figure 4: Sample deployment model for an eWALL cloud environment (Integration Test environment)

III. VALIDATION AND TESTING

Software testing is an important part of eWALL software development. Any incorrect human action that produces a problem in the system is called error. Deviation between expected behaviors to the actual behavior of the system is called defect. The deviation identified by end-user while using a system is called a failure. Presence of errors during software development results in defects and presence of defects results in failure of the eWALL system as a product. Figure 5 shows eWall integration work flow which consists of tools for build automation and deploy execution which should ensure error detection and avoid integration of components with errors.

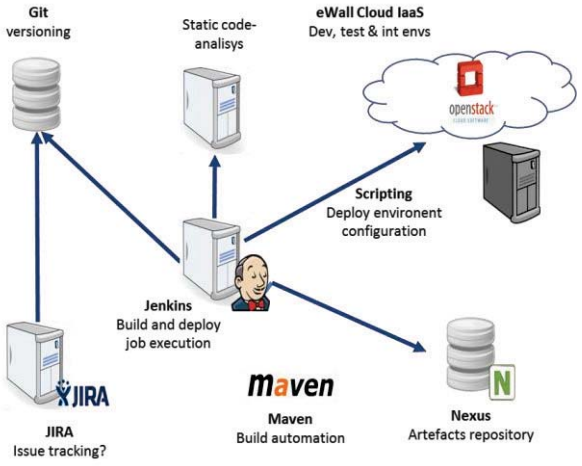

Figure 5: eWALL Integration work flow

Generally, software has defects because of incorrect requirements, wrong design, poor coding, complex logic, complex technology, work pressure or frequently changing requirements. Software testing is a process of verification, as well as of validation whether the exactly the wanted product is under development. Verification is a process known as static testing and validation as dynamic testing. Code review and unit testing are organized as part of development related work packages while integration testing and system testing are in scope of independent work group (WP6). System testing approach is based on traditional testing approach or positive testing which shows that the system does what it should. Most common defects are incorrect functionality, incorrect data edits, poor performance, poor security, incompatibility, poor user interface (UI) and poor usability. Objectives of testing are: to confirm whether the application is developed according to customer requirements or not, finding defects, to make sure all problems are resolved and close and help to deliver a quality product and risk-free product to the customer. Dynamic testing is carried out at following levels of testing: unit, integration, and system and user acceptance. The smallest separable portion in the source code of the application is called unit (functions, procedures, etc.). Testing conducted on these units (to check if the code behind the units is working as expected or not) is called unit testing. It is also called module testing or

component testing. Once all units are tested and integrated as wanted, the interactions among the units are checked, which called integration is testing. Unit testing and integration testing is collectively called white box testing. White box testing is helpful to reduce the defects as early as possible. Black box testing is conducted on the application by WP6 to check whether the application is working according to designed requirements. White box testing is conducted by a developer in a technical perception where as black box testing is conducted by test engineers with end-user perception. Programmers/developers will conduct white box testing in a positive perception whereas tester will conduct black box testing with a negative perception where there is a more chance of finding more defects. The more identified defects results in a quality system. White box testing will not cover non-functional areas. As functional requirements are also very important for production system, those are covered in the black box testing. WP6 uses functional system testing approach called smoke testing. It is a kind of quick test carried out on the application to determine whether the application is testable or not. Testing of software application by following all pre-plan procedures and proper documentation is called formal testing. Testing of the software without following any procedures and documentation is called ad-hoc informal testing. The critical functionality in the system and testing it first or conducting testing in the same order of priority is called risk based testing or priority based testing. Re-testing is testing functionality again or testing functionality repetitively. Re-testing comes in the following two scenarios: a) testing functionality with multiple inputs to confirm if the requested validations are implemented or not; b) testing functionality on the modified build to confirm that the bug fixers are made correctly. Regression testing is a process of identifying various features in the modified build where there is a chance of getting affected and retesting these features. The new functionalities added to the existing system or modifications made to the existing system or the bug fixes may introduce side effects. Regression testing helps to identify eventual side effects. End-to-end testing is testing the overall functionalities of the system including the data integration among all the modules. Testing conducted on an application unevenly or zigzag way with an intension of finding tricky defects is called monkey testing. Validating various non-functional aspects of the system such as user interfaces, user friendliness, security, compatibility, load, stress, performance, etc. is called non-functional system testing. Validation of professional design of user interfaces is called UI Testing. Check List for manual UI Testing: check if all basic elements are available in the page or not, check spelling of the objects, check alignments of the objects, check content displayed in web pages, check if the mandatory fields are highlighted, checks the consistency in the background color, font type and font size, etc. Usability testing means checking how easily the end user is able to understand and operate the application. Security testing is validating whether all security conditions are properly implemented in the software. Check list for security testing encompasses checking if the sensitive data such as password, credit card, CVV numbers are getting encrypted; checking the browser navigation after logout; checking direct URL access for the both secured and non-secured pages, checking for the session expiry; checking view source code option for secured pages; checking for the authorization; checking for authentication; checking the cookies. Performance testing is a process of measuring various efficiency characteristics of a system such as response time, throughput, load, stress transactions per minute and transaction mix. Load testing means analyzing functional and performance behavior of the application under various load conditions. Checking the application behavior under stress conditions is called stress testing; in other words, it means reducing the system resources and keeping the load as constant, while checking the behavior of the application. Checking the system ability to handle some unexpected or unpredictable situations is called recovery testing. Globalization testing is checking if the application has a provision of setting and changing languages, date and time format and currency etc. Installation testing is checking if the software was installed successfully, as per the guidelines given in installation document. Un-installation testing is checking of the software uninstallation ability from the system. Compatibility testing is checking if the application is compatible with the different software and hardware environment. Test planning is the first phase of system testing where the management plan the high level and detail testing activities to be carried out. Stakeholders responsible for validation and testing define test strategy and based on this test strategy the detail plan called test plan is prepared. Test strategy is high-level management plan and approach that provides sufficient confidence on the project being tested. Test plan is detail day-to-day work plan that explains scope, approach resources and work schedules etc.

IV. REQUIREMENTS AND CHALLENGES

Smoke testing

This type of side-effect regression testing is done with the goal of proving that a new build is not worth testing. Smoke tests are often automated and standardized from one build to the next. They test things we expect to work, and if they don't, we suspect that the program was built with the wrong file or that something basic is broken. Challenge is to find eventual errors as early as possible.

End-to-end testing

During the testing, functionalities are carefully examined. For the system to pass end-to-end testing, it needs to be functional and successfully started. The testing conducted can be divided into two different groups: deployment testing verifies successful deployment of proper versions; and functional testing verifies that every component is running and that basic functions are accessible. The main challenge is to ensure that entire eWall system is tested for critical functionalities such as communicating with the interfaces, database, network, and applications.

Usage-based Model testing
Requirement is to look at a system from the perspective of the states, transitions, events and actions that can describe its behavior. It can help identify a statistically efficient subset of those tests that might be worth running first. The automated testing process assumes to be a regular user and takes all the regular actions that a user can take on the system. Challenge is to find and define useful level of granularity.

Load and stress testing
Load testing is aimed at identifying the maximum operating capacity, detection of bottlenecks and measuring response times of a system. The tests are designed to reproduce the conditions where the system is at peak load conditions, but still fully operational. On the other hand, stress testing takes the conditions even further and tests the system above those peak conditions in order to determine the stability of the system and to detect its breaking points. The test scenarios for this group of tests are designed around repetitive tasks from a simulated number of users simultaneously using the application. It gets considerably more challenging to measure the scalability and performance of an interactive multi-user application. Doing so requires special tools and techniques, and a successful measurement and result is highly dependent upon a realistic assessment of the number of users and how they will use the application.

Automated performance tests for the Profiling Server
Screen Shot) – this can be used also for apps tests. Unlike Apache JMeter or SoapUI, these are totally web based (e.g. BlazeMeter records automatically app activity and saves it as JMeter script which can be loaded later or exported directly to Blaze Meter test).

Automated testing by Selenium IDE
Selenium IDE has been established for FireFox and Chrome. In FireFox it is useful to repeat previously recorded test cases. Challenge is to update test cases after changes on web pages and applications.
For the test, LoadStorm [3] is used (although there are plenty of alternatives such as LoadFocus [4], LoadImpact [5], Blitz [6], Loader [7], BlazeMeter [8] and ApiMetrics [9]). Also, the following performance test [10] gives a good overview (link is on results of Prof Server test, notice different fields: Summary, Details, Performance Review, Content Breakdown, Domain,

V. RESULTS OF TESTING

Testing and evaluation of the integrated prototype finished according to the plan of the eWALL project. Tests and integration become more complex and require systematic approach. List of tested applications is as follows: 0hn0 game, DFM, DPAM, HCM, memory card game, memory quiz game, memory test game, sleep, YouTube exercises portal, physical trainer application and eWALL-caregivers-web-app. Functionalities such us: fall detection, motivation messaging, presence detection, luminance, temperature, humidity, weather, notification manager, body motion, goal setting, exercising video, sleep monitoring, doors and windows, sanitary visitors services, voice and sound, messaging, admin tools and security protocols, Pulse, blood pressure and oxygen in blood are developed and implemented. The end-to-end testing finished with the OK status on 24 tests. There are 2 problems recorded in *Issue tracker* related to eWALL portal. Both recorded problems are marked with the "bug" and "minor" labels and milestone. In addition to the end-to-end testing, more than 200 tests were conducted. Requirements become complex as well as challenges. Testing becomes time-consuming work so we should implement in the next testing cycles more automated elements. In this project, we broke the myth that testing can be done by anyone.

VI. CONCLUSION

In process of delivering systems for independent living of senior citizens to end users, evaluation and testing play crucial roles. Main requirements in evaluation of the system are related to planning and execution of smoke testing, end to end testing, usage-based model testing, load and stress testing, automated performance testing. Challenge is to find eventual errors as early as possible and to ensure that entire eWall system is tested for critical functionalities such as communicating with the interfaces, database, network, and applications. In next development cycle we should consider modeling and simulation options due to some aspects of integration are complex to perform with the actual system. Pre-Configuration Management Testing and Post-Configuration Management Testing and implementation of standards for testing and documentation will enable decreasing of costs and increasing of quality of the eWALL system.

***Abstract*— Fishbone diagram is a tool used in Industries to identify the root cause of the problems. An attempt has been made in this paper to use this technique to identify problems in engineering education system in India, considering student as the stakeholder. Major problems are classified and fishbone diagram is used to analysis the root causes of each parameter.**

Keywords*— Fishbone diagram, Root cause analysis, Engineering education system, students problems.

I. INTRODUCTION

The current imbroglio in the teaching and learning process depends on the three major stakeholders; which are staff, students and the methods used to teach. In this scenario, the every stakeholder plays an equivalent role in the success or failure of the system. Thus, looking at all the three parameters this paper has initiated to do the root cause analysis in one of the most interesting parameter i.e. students. This paper deals with the problems arises in the lives of student in this circle of technical (engineering) education system. Analysis of the problems is going to be done with the help of the fishbone cause and effect diagram.

This method proves to be effective in order to reach the root cause of some issue. In this process there are major parameters; which acts as the main points or as a general term of one compiled problem and then on which further sub-issues are discussed. For example: this skeleton of a fishbone diagrams depict the causes of the problem until its root cause.

The outcomes that we expect from this analysis are we will be able to identify the ultimate or the root causes faced by the students. In this way, we will be able to propose a common solution their problems and also suggests education (Indian) system to upgrade their policies and methods. This paper makes an effort to mitigate the flaws in the technical Indian education system thus, increasing its efficiency and strengthening its position in the global education scenario.

II. LITERATURE REVIEW

A. Fishbone Diagram

The Ishikawa diagram is a tool to recognize the root causes of quality imbroglios. It was named after Kaoru Ishikawa, a Japanese quality control statistician, the man who pioneered the use of this chart in the 1960's. The Fishbone diagram is a process of breaking down the known truths that provides an orderly way of observing at result and the reason that account for those effects. Because of the intention of the Fishbone diagram, it may be delegated as a cause-and-effect diagram by Watson in 2004. Fishbone (Ishikawa) diagram mainly represents a model of suggestive presentation for the correlations between an event (effect) and its multiple happening

causes. The structure provided by the diagram helps team members think in a very systematic way[1].

Fishbone diagram is effectively used to reach the root cause of the problem. Some of the cases are discussed herewith. Jayswal et al. has used this to analysis of sustainable process of chemical/energy sector[2]. Quantification of risk assessment for FMEA analysis in processing industry[3].

Use of Fishbone in Educational sector is reflected in few cases. Reid[4] use this for categorising barriers of instructional technologies. Jih,Huang[5] used it for analysis of e-teaching. Use of 5why technique for questioning technique was done in Thiwan by Lu[6]. Problems in University colleges where analysed by Desai et al[7]. However the analysis is to be done in Indian perspective.

B. Scenario of Indian Engineering Education System

The pattern in the graduates passing every year is observed and is variable. However, this pattern changes in India. There are three variables – sanctioned intake (S), the enrolment (E) and the Output or Out-turn (O). These are defined as follows: (a) Sanctioned Intake - The AICTE approves the sanctioned intake of different engineering colleges in each state. This is for a given year. (b) Enrolment - The actual number enrolled (joining the course) may differ from the sanctioned strength. In many institutions all seats may not be filled. (c) Outturn / Output - The numbers that graduate each year. This is not reported on an all India basis. In some of the state reports (ATMRs) the annual output is reported for a few years.[8]

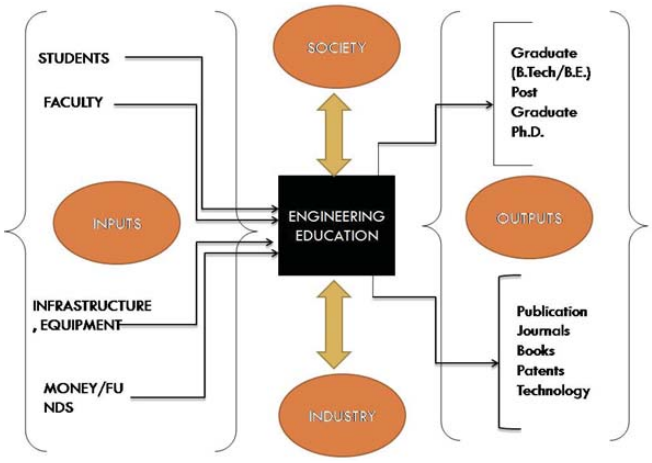

Fig. 1. Engineering Education in India[8]

The block diagram shown in Fig. 1 describes the Indian engineering education system. The four main stake holders are the society, industry, inputs and outputs. As engineering education is a professional technical degree which servers for four years course with many outcomes being either bad or good. The inputs are induced by students, faculty, infrastructure, money these are the factors which influence the engineering education system on a whole and further more joined by the society and the industry at regular intervals and all this resulting into the outputs shown in the figure namely the various degrees of graduation or the post graduation and the publications[8].

III. STUDENTS PROBLEMS WITH FISHBONE DIAGRAM

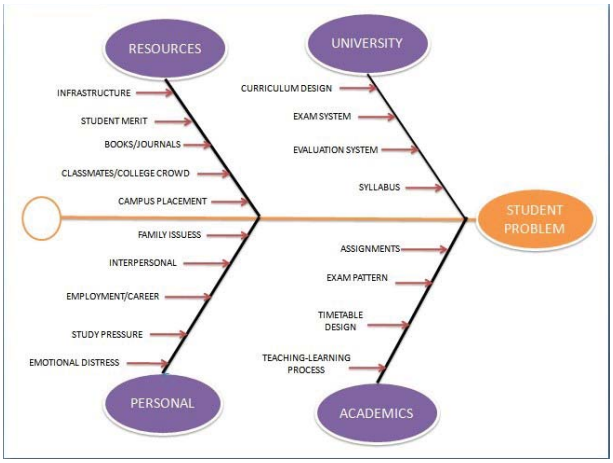

Fig. 2. Root Cause Analysis of Students Problems

The Fig.2 shows the root cause analysis of the student problems with the help of fishbone diagram. The main reasons are personal, universities, resources, academics. These main factors have sub-factors which takes us to the root cause of these problems.

A. Personal

Zhibin Chen reveals in his paper Psychological Problems and Countermeasures of College Students all the personal and psychological problems which a college student faces being in college. On further adaptation, the paper tells us that nowadays it's a very major issue in the college life to have these problems and many students are diagnosed with these disorders.

Zhibin jotted down few causes for these emotional unbalance in a student's mind. They were as follows: interpersonal tensions, Crises of employment and career prospectus, study pressure, Emotional distress, psychological expectations do not meet family, contemporary social impacts, inertia in inherent traditional educational models, family reasons, and traditional Chinese cultural factors. The above mentioned causes are relevant and do exists in the lives of student[9].

One more parameter that is to be considered is that there are no proper career councilors available for students to guide them in their journey to become a successful engineer. According to Lie Pan, Haiyan WU and Xun Wang career councilors say that access to information is the key to employment. There are various mediums to seek information like campus network, University Career Guidance Website, Job network, customized services. According to the authors student are keen to work and get employed but the only issue is they do not have the right platform to do so. They lack information and the seriousness of employment in the colleges while getting educated. Colleges should increase the propaganda of the employment issue right from the first year itself[10].

B. Academics:

The sub reasons that come under the academics as a stakeholder are as follows: 1. Assignments, 2. Exam pattern, 3. Timetable design, 4. Teaching and learning process. Now considering each pattern separately we get to know that the higher technical education demands the various assessments based to test a set of skill of a student on his problem solving skills, logic abilities, etc. The candidate has to solve these assignments and prove his worth in every assignment in order to get good grades in the term work grades and ace his exams. These assignments also reflect the student's capabilities to understand the topic. The assignments should be designed in such a way that they are good enough to test skills but not intimidate the student. However according to the author Rekha and Uma many a times home assignments are not taken seriously by the students and a lot of copying is involved thus making it unfair to grade their work[11].

Author as a student has an opinion that, students have an issue with assignments when excessive assignments are forced on them. To the point assignments which will reflect their abilities are considerable although just writing for the sake of assignments does no good. In the engineering education excessive assignments plays a key role in wasting the time of the student. However a good assignment if replaced with these unnecessary work; it will definitely help to improve the scenario of Indian engineering education. For this need of different technique to get the things done in more practical way is necessary, which can be done by Problem Based Learning (PBL).

Secondly, exam pattern is a very prime issue in understanding the difficulty to get good grades in the exam. Every student's perception of the getting adapted to the education system is different and also the estimated time for getting adjusted with the system may differ. This difference often results into the failure or a major setback for the student. Understanding the exam pattern is very important in order to write the exams. In universities over the time many patterns have changed which confuses the student to a larger extent. Students take time to understand exam pattern, which results in their gradation. They focus on scoring in exams but the actual conceptual study is missing. Thirdly, timetables play a crucial role in any academic system. A well designed timetable is always a key to more success stories in the engineering education. Timetables can be of exam as well as the daily scheduled lectures. Academic timetable should take care of basic workload as per the university guidelines, as well as it should take care of co-curricular and extra-curricular activities of the students. It should as well consider the time required for student upgrading and merging the gap between syllabus and present requirements from the recruiters. Both the timetables should be designed in such a way that they take care of all norms but are also student friendly, are designed by making student as the focus considering their study and work.

Lastly, another very important factor is the teaching-learning methods. Latest techniques of teaching-learning should be used like : PBL, e- Learning, ICT etc. In Indian education system traditional teaching method should be supplemented with these recent techniques for excellent results.

C. Resources

As like requirements of materials in industries, resources are required for education. One of the causes for student's failure is resources. This cause highlights the various shortcomings as college infrastructure, variation in students merit and tradition, books, journals etc.

The college infrastructure plays a vital role in the education of the students, if it's not well built than there will be obstacles in the overall development of the student. Some of the most basic necessary elements that a college campus should have are: well-equipped classrooms and laboratories, as the norms mentioned by the university syllabus. Library with sufficient books, journals, newspapers, magazines, e-library with access to online books and journals proves to be an important aid in education.

Classmates are also major reason for the student to be disinterested in the curriculum. If the college crowd is not good as in the students are not study oriented they affect the performance of the student as they might distract the student's focus from the studies and divert it elsewhere. This may happen if there is large difference in students merit during intake.

Campus placement also plays major role. Also access to industries through industrial visits, expert lecture series through industrial person, in-plant training, internship, projects is required for overall growth of the students. Some colleges fail to do so even they are advertising; this decays the moral of the students.

D. Universities

Role of universities is very important because the entire educational course is governed by it. Curriculum design is the most important parameter. Examination system and evaluation system also affects the output of the students. It should be taken care to match the syllabus with latest technologies.

IV. RESULTS AND DISCUSSION

By using Fishbone diagram, it is easy to reach till the root cause of the problem. Four major aspects of the source of problems are identified and causes of the same are discussed

Abstract: ***Burnishing is a simple, cost effective surface improvement process that not only improves surface finish but also surface micro hardness of the component. In burnishing process rotating ball or roller is pressed on the surface of the work piece beyond elastic limit of the material, so that plastic deformation of the material takes place, which induce residual stresses compressive in nature on the surface of the material.*** [1] ***The newly developed cost effective ball burnishing tool can be used on conventional lathe machine. By using the designed tool Surface micro hardness of 150.2 HV is achieved. Number of passes and depth of penetration proved to be the predominant parameters among the parameters studied.***

Keywords- Burnishing tool, Burnishing, Surface micro hardness, feed rate, number of passes

I. INTRODUCTION

The functional performance of a machined component, such as load bearing capacity, fatigue strength, wear resistance depends upon surface characteristics like surface topography, residual stresses, and hardness. The functional properties can be increased either by using new material or by means of surface plastic deformation process. Conventional surface finishing methods like grinding, honing, lapping especially depends upon chip removal to attain desired surface finish, these machining chips may cause further abrasion and geometrical tolerance problem, especially if conducted by unskilled operators.[2] Accordingly surface deformation process like burnishing offers an attractive post machining alternative due to its chip less and relatively simple operations. It not only improves surface finish of the material, but also improves surface hardness and in turn it increases fatigue strength, corrosion resistance and wear resistance of the material by inducing residual compressive stresses on the surface.[3] Based on literature survey, feed, speed, depth of penetration and number of passes are chosen as burnishing parameters. Kerosene is used as lubricant, throughout the experimentation. The effect of above parameters on surface hardness is studied. The ball burnishing mechanism is shown in fig. 1.

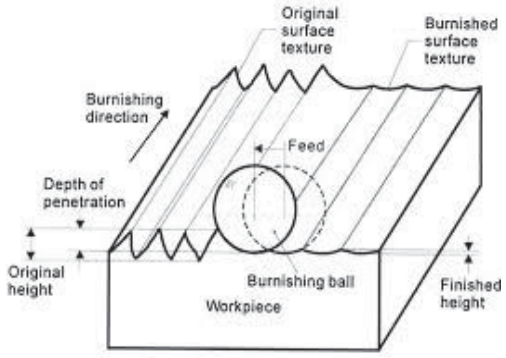

Fig 1. Burnishing Mechanism

II. LITERATURE REVIEW

N. H. Loh et al. explored effects of burnishing parameters like depth of penetration, feed, ball material and lubricant on surface hardness of AISI 1045 specimens. Based on their research the layer of maximum surface hardness lies beneath the burnishing surface. Grease gives maximum hardness of 331VHN. Hardness is increased by 68%.[4]

Fang-Jung Shiou et al used Taguchi L18 orthogonal array technique and ANOVA to investigate surface hardness value. Based on results, the hardness of the specimen, which was tested, increased to 480 on Vickers hardness scale from about 338 after ball burnishing process. The thickness of the harden layer was about 30 µm. By using the optimum values of burnishing parameters for plane burnishing to the surface finish of the freeform surface mold cavity, the surface finish improvement of the injection part on plan surface was about 62.9% and that on freeform surface was about 77.8%..[5]

N.S.M. EL-Tayeb et al. used Radial Basic Function for predicting Surface Integrity after burnishing. For prediction of surface roughness, they used artificial neural network (ANN) and radial basic function (RBF) techniques. Artificial neural networks are computing elements, which are based on the structure and function of the biological neurons. These networks have nodes or neurons, which are described by difference or differential equations. The nodes are interrelated layer-wise or intra-connected among

each other. Each node in the successive layer receives the inner product of synaptic weights with the outputs of the nodes in the previous layer when the vectors are binary or bipolar, hard-limiting non-linearity is used. When the vectors are analog, a squashed function is used.[6]

Adel Mahmood Hassan and Aiman Sharef Al-Bsharat studied the effect of burnishing process parameters on properties of material like surface roughness, hardness. It was found that surface hardness decreases with increase in feed rate and speed and increases with increase in force and number of passes. The percentage increase in surface micro hardness observed was around 60%. [7]

Aysun Sagbas analyzed effect of burnishing parameters on surface hardness of Aluminum 7178, using full factorial design nd analysis of variance. (ANOVA) Feed rate, burnishing force and number of passes were found as main burnishing process parameters to improve surface hardness. [8]

III. BALL BURNISHING TOOL

Ball burnishing tool is designed for conventional lathe machine. This tool is designed in such a way that ball can rotate freely. For this purpose instead of keeping ball on outer race of the bearing, 12 mm diameter ball is supported on 14 mm ball. Front adapter is also interchangeable, so that we can use ball of different diameters in the same tool. The spring is used to reduce sticking between ball and workpiece due to friction. To measure depth of penetration dial gauge is mounted on the tool, so that we can measure depth of penetration accurately.

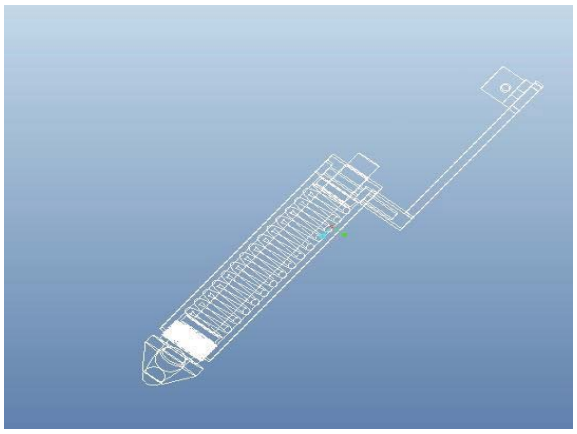

Fig. 2 Ball Burnishing Tool

IV. MATERIAL SELECTION

The experimental work is carried out to explore the effect of different ball burnishing process parameters on surface micro hardness of AA6351 alloy. Aluminum alloy is widely used in automobile and aerospace sector due to its properties like corrosion resistance, high strength to weight ratio. Aluminum alloy used for experimentation is most widely used alloy in wide variety of general applications in small scale industry as well as large scale industries. Aluminum is chosen as its weight to strength ratio is high and can be further improved by using burnishing process.

The composition of alloy and mechanical properties are given in Table 1 and Table 2 respectively.

Table 1: Composition of work material

Element	Cu	Mg	Mn	Si	Fe	Al
Weight %	0.1	0.4 - 1.2	0.4 - 1.0	0.6-1.3	0.6	Remainder

Table 2 Material Properties of work material

Density g/cc	Tensile Strength Mpa	Yield Strength Mpa	Hardness, HB	Modulus of Elasticity , GPa	Poisson's ratio
2.6-2.8	250	150	95	70-80	0.033

V. SPECIMEN PREPARATION

Solid bars of AA6351 Aluminum alloy of 26 mm are taken and turned on lathe machine as shown in fig below, keeping all process parameters same while turning all specimens.

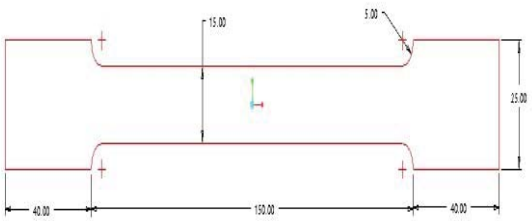

Fig.3 Specimen

VI. EXPERIMENTATION

5.1 Process Parameter Selection:

The factors and their levels are shown in table 3. Feed, speed, depth of penetration and number of passes are adopted as factors which vary during experiments. The values of the factors are decided based on pilot experiment carried out.

Table 3: Levels of factors for experiment design

Factors / Levels	Code	Low(-)	High(+)
Feed Rate (mm/Rev)	A	0.04	0.051
Speed (rpm)	B	800	900
Depth of Penetration(mm)	C	0.50	0.75
No. of tool passes	D	1	2

For each factors, two levels are deliberately chosen and set during experiments according to the DOE. Table 4 shows the selected design matrix. All these data were utilized for the analysis and evaluation of optimum parameter combination required to achieve desired surface micro hardness within the experimental domain.

Table 4: Design of Matrix and Results

Run	Actual Values				Surface Micro hardness value (After Burnishing)
	A	B	C	D	
1	0.04	800	0.50	1	142.9
2	0.04	800	0.50	2	143.4
3	0.051	800	0.50	1	144.8
4	0.051	800	0.50	2	140.6
5	0.04	900	0.50	1	142.4
6	0.04	900	0.50	2	146.8
7	0.051	900	0.50	1	144.7
8	0.051	900	0.50	2	145.9
9	0.04	800	0.75	1	147.7
10	0.04	800	0.75	2	144.8
11	0.051	800	0.75	1	143.4
12	0.051	800	0.75	2	150.2
13	0.04	900	0.75	1	145.7
14	0.04	900	0.75	2	146.9
15	0.051	900	0.75	1	142.5
16	0.051	900	0.75	2	145.7

Experiments were carried out based on experimental design matrix. The experimentation for burnishing operation is done on conventional lathe. The surface roughness measurement is done on surface tester. Table 4 shows selected design matrix based on Taguchi L16 orthogonal array consisting of 16 sets of conditions. All this data is used for conduction of actual experimental work on lathe. Experimentation is done on experimental matrix developed by Minitab 15 and results are evaluated for surface micro hardness of AA6351 Alloy. The objective of the present work is to explore the effect of feed rate (mm/rev), speed (rpm), depth of penetration (mm) and number of passes on AA6351 alloy. In this investigations "surface micro hardness" is typically chosen as response variables. The entire investigation is carried out on conventional lathe machine.

Fig. 4 Experimental Setup

Fig. 5 Burnishing Process

Table 5 Effect of Different Parameters

Factors	SS (Sum of Squares)	DF (Degree of freedom)	MS (Mean Square)	F (Variance Ratio)	% P (% Contribution)
A (feed rate)	0.0582	3	0.0160	1	1.358
B(speed)	0.1145	3	0.0378	2.37	3.263
C (depth)	2.2570	3	0.7503	46.79	64.71
D (passes)	1.0964	3	0.3588	22.48	30.88
Total	3.5241	12	1.1629		

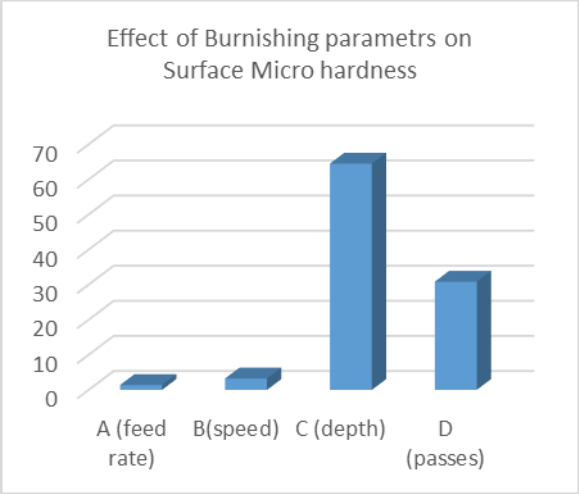

Fig. 6 Effect of Different Parameters on Surface Micro hardness

VII CONCLUSION AND DISCUSSION

1. The micro hardness value depends on burnishing parameters. Depth of penetration and number of passes are the major parameters in improving surface micro hardness of the material.
2. Depth of penetration is the predominant parameter among the parameters taken during experimentation. Its contribution is 64.717% among the parameters taken.
3. Along with depth of penetration, number of passes also plays role in improving surface micro hardness. (30.88 %)
4. It is also observed that if initial surface roughness is more, amount of plastic deformation will be more and hence surface micro hardness will be more.

VIII FUTURE SCOPE

The burnishing operation is successfully carried out on AA6351 Alloy which shows the improved results for surface finish as well as surface micro hardness. Following work can be carried out to check other properties of alloy.

1. Empirical models can be developed for surface hardness as well as other properties of material.

2. FEM analysis can be carried out, so that we can predict the surface roughness, micro hardness, residual stress etc.

3. By changing ball material and ball diameter better surface quality can be achieved.

4. Optimization of parameters can be done to improve surface integrity of material.

***Abstract*— in the current scenario of industries, the product mix and demands are very frequently changing and so the quick response is expected from industry. Layout design has a significant impact on manufacturing efficiency. A static plant layout if possible to be converted to dynamic layout may improve the efficiency of the plant significantly. Dynamic layout is a layout, which can be rearranged with respect to time as per variation in product design, quantity, and change in product mix. Dynamic layout problem is a quadratic assignment problem and is of non-deterministic polynomial-time (NP) hard problem. In this work, real coded genetic algorithm (RCGA) is applied to solve benchmark problem in dynamic layout, which gives better results than the reported.**

Keywords—Dynamic layout, Real coded genetic algorithm.

I. INTRODUCTION

Layout planning gives a significant impact on the performance of a manufacturing or service industry system, and consequently has been an active research area for several decades. Layout is the arrangement of facilities, machines, or departments in the plant, such that it makes it convenient for movement, operations of man, material and reduces the material handling. Generally, once the plant layout is finalized, it is not changed. This type of layout is called as static layout. However, in due course of time, because of change in product quantity or product mix or change in product itself, the static layout may not remain optimum. It may result in more material handling cost and more time or delay. So, to overcome this problem, if the layout is changed from time to time; with respect to change in product mix or quantity such layout is called as dynamic layout. In today's challenging conditions, frequent changes in the products, product mix, and quantity, the static layout may not be effective, as it will result into more material handling and subsequently higher material handling cost. Therefore, it is essential to consider the dynamic approach in such cases to increase the effectiveness of the plant.

Dynamic layout problem becomes more and more complex as the number of departments and the number of time periods are increasing. It is non-deterministic polynomial-time (NP) hard problem [6] and generally, this problem is formulated as quadratic assignment problem (QAP). Many times solving the complex dynamic layout problem is difficult with traditional methods of optimization [27]. Hence, the researchers are attempting metaheuristics such as Genetic Algorithm (GA), Simulated Annealing (SA), and Tabu Search (TS) etc. for solving dynamic layout problems. The dynamic layout problem has wide applications in industries where the product mix is highly prone to change according to the market demand. Developments in the materials and machine handling technology are very useful for changing the layout frequently. In this paper benchmark problems are solved using RCGA.

II. LITERATURE REVIEW

Traditionally layout planning is treated as strategic decision, which once implemented is difficult to modify. Advent of new material handling technology and materials used for manufacturing of modern machine tools has changed the perspective of layout planning. Development of mathematical models and use of recent and powerful problem solving methodologies proved to be very useful to improve the effectiveness of plant operations. Various researchers have tried to solve the dynamic layout problem using various approaches as discussed in this section.

Lenin et al. [25] have presented a genetic algorithm approach, to find out machine's linear sequence with multi products and different operation sequences for static layout. They have tried to minimize the total flow distance travelled by the product. They have generated some problems and their approach was compared with other approaches. Presented approach was found to give results that are more favorable. However, they have not considered the dynamic conditions and only virtual problems are considered. Brunese and Tanchoco [9] have studied single row machine layout problem with the within building constraints, because of which they could get improved quality of solutions in reduced time. To achieve these results authors have used nonlinear and mixed integer formulations. However, they have not considered the multi row layout and dynamic conditions. Bock and Hoberg [8] have planned layout in more detailed way, by considering

machine layout and transportation paths simultaneously. They have introduced new mathematical layout model and suggested several solution procedures to solve it. Promising results are obtained to the author when it was tested with randomly generated instances. However, the authors have used randomly generated instances and have not considered the dynamic conditions and real life industry problems. Goncalves and Tiberti [17] have proposed a new approach of genetic algorithm, for the machine cell layout design. It is working on group encoding instead simple machine encoding, also new crossover and mutation operators are suggested. The tests show that the algorithm is able to disclose the group structure. However, the authors have not considered the changing product mix and quantity. Solimanpur and Kamran [34] have assumed a shop floor with multiple products, on multiple machines; and the alternate processing routes are considered to minimize total distance travelled by material. Genetic algorithm is applied to solve this problem. The effectiveness of the approach is evaluated by numerical example and results show that applied GA is effective and efficient. However, the applied approach does not consider the changing demand.

Above review shows that most of the researchers have considered the static nature of layout for optimization. However, current scenario of industry shows the trend of changing demand, change in product mix and quantity. Therefore, to cope up with this changing scenario it is necessary to consider dynamic layout concept. Though dynamic layout is a new approach to industry, few researchers have worked on it.

Moslemipour and Lee [32] have suggested QAP formulation to solve Dynamic machine layout problem in flexible manufacturing system (FMS). They have considered the variation in product demand for changing the layout and have solved two randomly generated dynamic problems. These are solved with SA approach and have obtained satisfactory results. However, the problems they have considered are computer generated and virtual. Donga et al. [11] have studied dynamic multistage facility layout problem, in which new machines can be added or removed at different planning periods. They have proposed and used an auction algorithm, which is based on SA algorithm. To illustrate the proposed methodology an industrial case of 4 periods and 56 machines are employed. The results obtained are efficient. However, for discrete category problems, GA approach is more useful. Azimi and Charmchi [4] have suggested a new heuristic algorithm, which is developed by combining mathematical programming and simulation methods for dynamic facility layout problem with budget constraint. Proposed algorithm was tested over wide range of problems and the improved results were obtained. However, real case study needs to be solved. Mohammadi and Moghadam [31] have studied dynamic machine layout for automotive shop; and suggested a model to solve it. A problem of seven machines and seven-time periods is assumed, and satisfactory results are obtained. However, they have not considered the changing product mix. Ashthiani et al. [3] have discussed the dynamic plant layout problem. They have proposed multi start simulated annealing approach to solve this problem. To compare the performance of the approach some data sets are selected from the literature and the results show good performance. Krishnan et al. [23] have developed 'Dynamic from between chart' approach to solve dynamic plant layout problem. A case study from Aircraft Company has been considered for verification of approach. However, they have not considered machines layout. Ahin and Turkbey [2] have presented a new approach 'TABUSA' to solve the dynamic facility layout problem. The presented heuristic is based on simulated annealing approach supplemented with tabu list. The efficiency of the approach is tested against the data sets from literature. Baykasoglu and Gindy [7] have used SA to solve dynamic layout problem. Some problems from literature are solved and the results are compared. Jinde and Telsang [21] apply a genetic algorithm approach to electrical motor manufacturing company to minimize material handling cost between machines. The problem is formulated in QAP and the results show that GA approach is performing well. However, the authors have considered static layout problem only.

Above literature, review shows that most of the researchers have worked on design of plant layout, using various algorithms and various approaches. Still there is scope to consider dynamic machine layout problem. With various changing parameters, real coded genetic algorithm can also be seen as new approach for solving these problems.

III. Presented Approach

When the flow of material between departments changes during a planning horizon, the static layout problem (SLP) becomes dynamic, and this problem is known as the dynamic plant layout problem (DPLP). The DPLP is based on the anticipated changes in flow that can occur in the future. The prospective future is divided into a number of time periods and the period may be defined in weeks, months, etc. The solution for the SLP is a single layout, and the solution for the DPLP is a series of layouts, where each layout is associated with a particular period. This problem is of the category of NP hard problem. [27]

A. Mathematical Formulation

The above problem is more commonly formulated as the QAP, and it is taken from Balakrishnan et al. [6], where minimizing total material handling cost Z is the objective function, it can be expressed in terms of the variables like f, d, and t.

$$\text{Min } Z = \sum_{p=1}^{P}\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n}\sum_{l=1}^{n} f_{ikl} d_{ijl} X_{ij} X_{kl} + \sum_{p=2}^{P}\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n}\sum_{l=1}^{n} A_{ijl} Y_{ijl} \quad (1)$$

Subject to,

$$\sum_{i=1}^{n} X_{tij} = 1, \quad j = 1,\ldots,n, \quad t = 1,\ldots,P \qquad (2)$$

$$\sum_{j=1}^{n} X_{tij} = 1, \quad j = 1,\ldots,n, \quad t = 1,\ldots,P \qquad (3)$$

$$Y_{tijl}=X_{(t-1)ij}*X_{til}, \; I,j,l=1,\ldots n; \; t=2,\ldots,P \qquad (4)$$

Where
P : Number of time periods in planning horizon
n : Number of machines in the layout
i,k : Machines in the layout
j,l : Locations in the layout
f_{ik} : Flow cost from machine i to k
d_{jl} : Distance from location j to l
Y_{tijl} : 0,1 variable for shifting i from j to l in period t
X_{tij} : 0,1 variable for locating machine i at location j in period t
A_{tijl} : Cost of shifting from j to l in period t. ($A_{tijj} = 0$)

Equation (1) is the addition of the material flow cost and layout rearrangement cost at the planning horizon. Equations (2) and (3) state that every machine must be located and each location must be occupied in every period. Equation (4) states that the 0-1 departmental rearrangement variable takes on a value of 1, only if at the end of a period machine shifts its location.

There can be *N!* possible layout arrangements, for *N* machines. Enumeration of which is a very difficult approach to solving the QAP. However, as the problem size *(N)* increases, the number of possible arrangements (*N!)* also increases. This approach aims for good solution, which is indicated by solution obtained in shortest processing time and comparable to results obtained by other algorithms. Hence, the goodness of any solution approach is adjudged against known example problems, for which the best solutions have been claimed.

B. *Real Coded Genetic Algorithm*

Goldberg [15], has discussed the approach for binary and real coding of GA. GA imitates the mechanism of the natural selection and evolution and aims to solve an optimization problem with object function *f(x)* where $x=[x_1\ x_2\ \ldots\ldots\ x_n]$ is the N-dimensional vector of optimization parameters. For any combinatorial optimization problems, it has proved to be an effective and powerful global optimization algorithm, especially for discrete optimization parameters, non-differentiable and discontinuous object function.

Binary GA is made up of *genes* and *chromosomes*. Binary code string is used to encode the optimization parameters in conventional binary GA. A binary bit is called as a gene in GA. While dealing with continuous search spaces with large dimensions, and in the requirement of high numerical precision, Real coded genetic algorithm (RCGA) possesses many advantages over its binary coded counterpart. Each gene represents a variable of the problem in RCGA, and the size of the chromosome is kept the same as the length of the solution to the problem. Without sacrificing precision, RCGA can deal with large domains unlike the binary implementation (assuming a chromosome of fixed length). In addition, RCGA possesses the capacity for the local tuning of the solutions; it also allows integrating the domain knowledge to improve the performance of genetic algorithm (GA).

The binary GA does not operate directly on the optimization parameters but on a discretised representation of them. Discretization error will inevitably be introduced when encoding a real number. The operations like encoding and decoding also makes the algorithm more computationally expensive when the problem uses real optimization parameters. Both practical experiences and theoretical proof show that RCGA usually works better than binary GA, especially for problems having real optimization parameters. [19]

The RCGA operates on chromosome population (or creatures, individuals, etc.) simultaneously. It starts from an initial population, and randomly generated within the search space. Once initialization is completed, the population enters the main RCGA loop and performs a global optimization for searching the optimum solution of the problem.

GA has some limitations such as all offspring are accepted and their parent strings are abandoned at the end of every generation regardless of their fitness values. Because of this, there is a risk of replacing good parent strings with deteriorated child string. However, in the methodology of RCGA presented in this paper, the good parent strings are also restored with the good child strings and the care is taken that both good parent and child strings will go to the next generation. Another limitation of GA is that only good parents are given chance to produce the offspring, this is also taken care in the methodology of RCGA, as roulette wheel selection is employed the chance is given to all parent strings. Hence, the answers obtained are near optimal.

C. *Algorithm for RCGA*

Step 1:- The parameters like Probability of *Crossover (p), Probability of Mutation (q), population size and termination criteria* are defined.

Step 2: -A set of possible solutions called the *"Initial Population"* is initialized such that the values range uniformly throughout the search space.

Step 3:- The *Fitness Values* are calculated for each of the individuals and the population is sorted in the decreasing order of the fitness.

Step 4:- Using the "*Roulette Wheel*" method of *'Selection'*, few individuals are selected to undergo *crossover*.

Step 5:- According to *Crossover Probability* the *'Crossover'* between two individuals produces two '*Child Chromosomes*'.

Step 6:- Then using the '*Probability of Mutation'*, a few individuals are mutated.

Step 7: At the end of performing crossover and mutation, we obtain the crossover and the mutated child individuals. These along with the parent population form super set for the next generation population.

Step 8:- The Steps 3 to Steps 7 are repeated until the '*Termination'* condition is reached.

Step 9: The population obtained at the end of the specified number of iterations is the outcome of this process.

IV. Application of Algorithm

Here, an example is considered, which is a standard benchmark function for dynamic layout problem [33].

Example :

Standard benchmark function for dynamic layout problem with 6 machines and 5 periods given by Rosenblatt M. J.[33], is shown in Table 1. It shows the flow between the machines. The distances between the machines are assumed to be one unit and the layout is of 2 rows and 3 columns. To this problem, RCGA is iterated for 100 generations and the population size is 50. Crossover probability is 0.7 and mutation probability is 0.2.

Table 1 Standard benchmark function given by Rosenblatt [33]

Period 1

To -- From	1	2	3	4	5	6
1	0	63	605	551	116	136
2	63	0	635	941	50	191
3	104	71	0	569	136	55
4	65	193	622	0	77	90
5	162	174	607	591	0	179
6	156	13	667	611	175	0

Period 2

1	0	175	804	904	56	176
2	63	0	743	936	45	177
3	168	85	0	918	138	134
4	51	94	962	0	173	39
5	97	104	730	634	0	144
6	95	115	983	597	24	0

Period 3

1	0	90	77	553	769	139
2	168	0	114	653	525	185
3	32	35	0	664	898	87
4	27	166	42	0	960	179
5	185	56	44	926	0	104
6	72	128	173	634	687	0

Period 4

1	0	112	15	199	665	649
2	153	0	116	173	912	671
3	10	28	0	182	855	542

2	820	0	5	98	141	66
3	822	650	0	137	78	91
4	826	570	149	0	93	151
5	915	515	53	35	0	177
6	614	729	178	10	99	0

Shifting cost for departments

887	964	213	367	289	477

Table 2 shows the analysis of above problem, when solved with presented RCGA and the results obtained for the problem provided by Rosenblatt using Dynamic programming. For the above problem, if static layout is applied then the cost obtained is $ 78,374; and as if the machines are not changing their positions, its rearrangement cost is zero. However, for all time periods, the layout is non-optimum, so the material handling cost is high. The presented RCGA approach is giving 5.56% better results as compared to the reported answer. In reported answer the material handling cost is less as compared to present approach; but the machines rearrangement cost is more in the reported answer, which is $75,384. So the total cost obtained ($ 71,187) by presented approach, is less than the reported answer.

The objective function Z, is represented by the 'Total cost', column in the above table. Above comparison shows that the dynamic layout approach is definitely saving the cost as compared to the static layout approach. In addition, it shows that machines rearrangement cost is equally important as that of material handling cost. Total cost is comprising of machines rearrangement cost and material handling cost.

Table 2 Result and analysis of optimization for dynamic layout problem [33]

Approach	Machine Positions	Machines Rearrangement Cost ($)	Material handling cost ($)	Total Cost ($) (Z)
Static	For all time periods 1 2 3 4 5 6	--- --- --- --- --- Subtotal	15,403 18,617 15,156 14,659 14,539 78,374	78,374
Dynamic (by Rosenblatt using dynamic programming)	1st time period 1 3 5 6 4 2 2nd time period 1 4 2 5 3 6 3rd time period 1 5 3 2 4 6 4th time period 1 6 4 2 5 3 5th time period 3 2 6 4 1 5 Subtotal	--- 2,310 1,833 1,346 3,197 8,686	12,822 14,853 13,172 13,032 12,819 66,698	75,384

(RCGA)	1 5 3 2 6 4			
	5th time period	1,364	13,867	
	6 5 3 2 1 4			
	Subtotal	2,710	68,477	**71,187**

V. CONCLUSION

Dynamic machine layout concept is useful in the industries where product mix and product quantity are changing with respect to time. In this work, real coded genetic algorithm (RCGA), is applied to benchmark problem and it is observed that the better answer is obtained than the reported in the literature. This clearly indicates the potential of this approach to solve dynamic layout problems.

ABSTRACT :

To increase productivity and operational efficiency maintenance management & reliability engineering, now gaining more and more importance, as upkeep of all the equipments in manufacturing industries becomes essential. It is very easy to say do maintenance, but it is really very tricky to decide the optimum policy of preventive maintenance and replacement that can result into minimum maintenance cost.

A case study in process industry is discussed to develop the model for preventive maintenance and replacement policy. FMEA analysis is done to prioritized the system with high risk. This identified high risk system further drilled down to know the root cause of failures and corrective actions to be taken.

Further a model is developed for total maintenance cost. Replacement cost and preventive maintenance cost is considered for total maintenance cost. It is optimized by using interval halving method.

I. INTRODUCTION

Due to continuous use of equipment, deterioration with age and usage is natural phenomenon. This equipment or part deterioration can take various forms such as wear, breaking, cracking or fracture etc. This ultimately results in to equipment failure and equipment could not perform its desired function. Avoiding this equipment failure and controlling its deterioration is essential.

Due to cut through competition in the manufacturing sector, no organization can afford any type of manufacturing delay or equipment failure (losses). Hence it becomes essential to focus on identification and measurement of losses and its control. One prominent area, where losses can occurred, is maintenance. Although maintenance is previously considered as secondary function, now a days it becomes important supporting function if treated properly can results in productive tool to increase production rate and reduce six big losses or equipment failure. These six big losses are breakdowns, downtime, setup and adjustments, small stops , reduced speed, start up rejects and production rejects. This six big losses can be grouped into three main subgroups. First is availability includes breakdown and downtime losses. Secondly performance considers small stops, reduced speed, setup and adjustments. Third is quality it includes startup rejects and production rejects. All these aspects can be measured with single performance measuring parameter Overall Equipment Effective Effectiveness (OEE). OEE is introduced by Nakajima in 1988 as first objective of Total Productive Maintenance (TPM). It is a single parameter indicator , that covers all six big losses. In Total Productive maintenance a key issue is to decide the frequency of PM and the time of replacement to minimize total cost of maintenance. In this paper an attempt is made to find out these optimum values. This paper is concluded with specific values of PM frequency and replacement time with minimum total maintenance cost.

II. LITERATURE REVIEW:

Yeh and Sun 2011 establish a model to maintain the key equipment in a semiconductor factory, based on its history of preventive maintenance (PM) and applying Monte Carlo simulation to predict the probability of the next PM time-point. According to the results of this study, businesses could establish an effective maintenance model, standardize a regular maintenance plan and the maintenance arrangement and prediction, provide the setting control and the alerting specifications as the referral index of maintenance time-point for the manufacture and the equipment engineering departments to achieve 85% Overall Equipment Efficiency (OEE).

Sobamowo *et al*. 2012 develops optimal preventive maintenance models using Weibull Distribution to predict maintenance models for Eglin steam turbines. They imply that it is more expensive to perform a preventive maintenance at the inception of a preventive maintenance cycle. The cost decreases as the cycle increases. It is worthy to note that there exist an inverse relationship between the total cost of replacement and the cycle length. It reveals that for an increasing cycle length, the total cost of replacement per unit

turbine becomes constant. Also, the downtime continues to decrease until it gets to a very minimal level before it becomes steady.

Chitakala and Sukumari 2014 developed the Preventive replacement strategy for determining an optimal replacement time for an automobile system that deteriorates with time is proposed and investigated, while the part of the system is in the final stages of its life span. The failure time followed the Weibull distribution and hence the optimum replacement time can be determined. This time minimizes total downtime and maximizes the proportion of time the parts of the system available.

Chang 2014 proposes the preventive replacement policy for an operating system which may continuously work for N jobs with random working times and be imperfectly maintained upon failure.

From above literature review it is clear that more focus must be given on deciding the frequency of preventive maintenance (PM) and appropriate time of replacement. In this paper an attempt is made to find out optimal frequency of PM and replacement to make the maintenance process cost effective.

III. METHODOLOGY

Case Study: A case study in process industry, engaged in manufacturing of electrodes is discussed to elaborate the nature of problem and its proposed methodology to solve the same.

The electrodes are manufactured with the raw material having particle size ranging from 5-8 cm diameter. Initially the raw material is crushed, sized and milled. The degree to which the coke is broken down depends on the grade of electrode to be manufactured. Raw material is mixed after the desired proportion in charging bins is established. The purpose of mixing is to blend the coke filler materials and to melt and distribute the pitch binder over the surfaces of the filler grains. The degree of mixing depends on factors such as time, temperature and batch size. The hot mix must be cooled to a temperature slightly above the softening point of the binder pitch. The forming and extrusion press produce a article that can withstand at high tamping pressure.

Data Collection:

Above mentioned process involved three main sub system crushing, extrusion and pitch and scrap system. Eleven moth breakdown data is collected as shown in table no 1

Thus from above table no. 1 it can be observed that out of these three system Extrusion system faces more breakdown i.e. 185.5 hours as compared to other system.

TABLE I: MEASUREMENT OF BREAKDOWN HOURS (DOWNTIME) FOR THREE SUB SYSTEMS DURING APRIL 13 TO MARCH 14

Months	Crushing System	Extrusion System	Pitch & Scrap System
April	2.5	17.25	1.75
May	1.5	16.25	1.5
June	2.5	12.75	2.5
July	3	13.5	1.5
August	5	16.25	1
September	4.75	14.75	2.25
October	3.5	17.25	1.5
November	2.25	18.75	2
December	2.5	14.25	1.25
January	4.5	20	1.5
February	3.5	11.5	0.75
March	3.75	13	1
Total Hours	39.25	**185.5**	18.5

Hence this extrusion process is further studied to know root cause of higher breakdown hours.

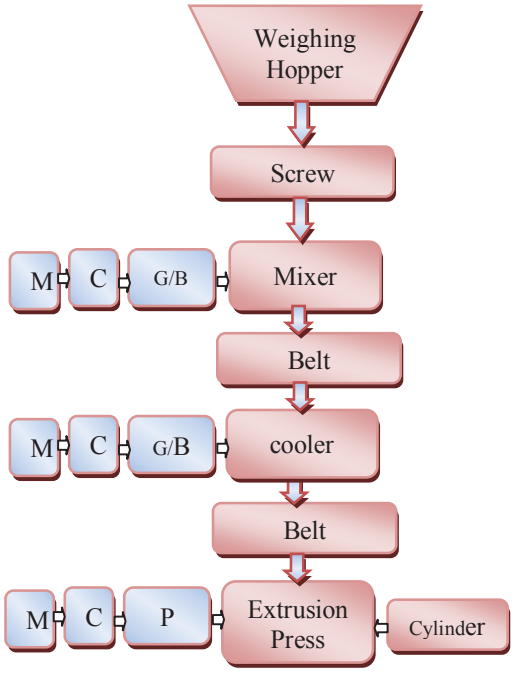

Fig.1 Block diagram of Extrusion System

In Extrusion system green electrode is extruded from press and delivers to next department for further processing. In Extrusion system CPC (Calcanide petroleum coke), Binder Pitch, Ferric oxide and oil are weighted as per recipe then through screw conveyor, the recipe means one charge weight is discharged into mixer where it is

heated and mixed up to 160 to 170° C, then from mixer it is delivered to cooler through belt conveyor where the charge is cool down up to 100 to 110° C then through belt conveyor the charge is discharged into extrusion press where electrode is extruded. Detailed breakdown hours for various components of extrusion system in weeks are given in table II

TABLE II: EXTRUSION SYSTEM COMPONENTS FAILURE (HOURS)

Month	Motor	Coupling	Gear box	Valves	Cylinder	Pump
1	6.25	4.25	3.25	1.25	2.75	3
2	6	4.5	0	2.25	2	.5
3	1.5	2.75	0	1.25	2.5	.5
4	0	4	3.75	2	4	0.25
5	5.25	2.5	1.5	0.5	0.5	1.5
6	0.75	2	3.5	1	2.5	0
7	1.75	1.75	1.5	2.75	5.75	0
8	1.25	2.5	2	3.5	0.5	1.75
9	1	0.75	0	0.75	1.5	0.5
10	0	3.75	2	0.75	2.75	1.25
11	2	4.75	2.5	1.5	1.5	3.75
12	3.5	4	2.5	0.75	2.5	0
13	2.75	4	0	1.50	2.5	1.5
Total	**28.5**	**41.5**	22.5	19.75	**31.25**	14.5

From the history of breakdown failure data in table II, it has been observed that coupling is most critical component as its breakdown hours are highest i.e. 41.5 hours as compared to other component or sub assembly .Thus coupling is identified component for further study. Failure mode and effect analysis (FMEA) is used to identify, analyze and suggest corrective actions to reduce failure of coupling. The severity of failure is measured in terms of risk priority number (RPN). Higher is RPN higher attention must be provided to reduce its risk.

TABLE III: RISK PRIORITY NUMBER CALCULATIONS

Sr. No	Component	SEV	OCC	DET	RPN
1	Coupling	8	9	7	504
2	Cylinder	7	9	7	441
3	Motor	6	8	8	384

RPN= SEV * OCC*DET

SEV= Severity, OCC= Occurrence & DET= Detection of faults

From table III, it is clear that coupling of extrusion system is more critical and risk priority of it is 504. Hence it is essential to reduce RPN of 504 to reduce the breakdown hours of the entire system. By reducing breakdown hours corresponding maintenance cost can be reduced.

IV MATHEMATICAL MODEL FOR PREVENTIVE MAINTENANCE AND REPLACEMENTS

For a new system, one need to find cost associated with a given schedule of future maintenance and replacement activities. The cost associated with all component level preventive maintenance (n) and replacement (m) actions in period (t), will be a function of the all the actions taken during that period.

1 Preventive Maintenance Cost (C_{pm})

If maintenance is performed on component ' i ' in period ' t ', a maintenance cost constant C_{pm} is incurred at the end of the period.

2 Replacement Cost C_{rj}

If component 'j' is replaced in period 't' we assume that the replacement cost is the initial purchase price of the component 'j', denoted **(C_{rj})**

3 Total Cost $f(x)$

From advantage point at the start of the planning horizon, we wish to determine the set of activities, i.e., maintenance, replacement for each component in each period such that total cost is minimized. And from definitions of each type of cost, the following total cost function is derived.

$$\textbf{Total Cost} = \sum_{i=1}^{n} \boldsymbol{Cpm_i} + \sum_{j=1}^{m} \boldsymbol{Cr_j} \quad [1]$$

This objective function computes the total cost as a summation of component costs in each period based on preventive maintenance or replacement cost and the system downtime cost.

Optimization Model

The mathematical foundation for solving models arising from the proposed modeling framework is Interval Halving technique. The algorithms described in this section can be used to solve minimization problems of the following type:

Minimize f(x), Where f(x) is the objective function and x is a real variable. The purpose of an optimization algorithm is to find a solution x, for which the function f(x) is minimum.

Interval Halving method

Figure 2, shows a region in the interval (a, b). Three points divide the search space into four regions .The fundamental rule for region elimination is used to eliminate a portion of search space based on function values at three chosen points.

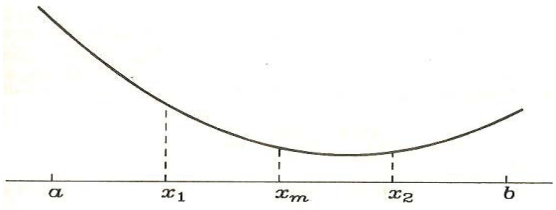

Figure 2 Three points x_1, x_2, x_m used in the interval halving

Algorithm:

1. Choose lower bound 'a' and upper bound 'b' and small value $\in$ for desired accuracy $X_m=(a+b)/2$ and $L_0= L= b-a$, compute $f(X_m)$
2. Set $X_1 = a+ L/4*(X_2)=b-L/4$ compute $f(X_1)$ and $f(X_2)$
3. If $f(X_1)<f(X_m)$, $X_m =X_1$
Set $b =X_m$ go to Step5, else go toStep4.
4. If $f(X_2)< f(X_m)$ set $a= X_m$, $X_m = X_2$ go to step 5
Else $a= X_1$, $b= X_2$ go to Step5.
5. Calculate L= b-a if $|L| < \in$ If terminates, else go to step2.

The objective function is to find out optimal Preventive maintenance and replacement frequency with minimum cost the following data is collected from SAP & Log book.

TABLE IV: NUMBER OF PM & COST OF PM

PM (n)	Cost of PM (*Cpm*) in Rs	Summation of PM cost (*Cpm*)
1	1379.8	1379.8
2	1803.13	3182.9
3	2478.9	5661.8
4	2889.45	8551.2
5	3376.35	11927.5
6	3928.6	15855
7	3685.75	19540
8	4567.25	24107

The frequency and cost of PM is as per above table. To use regression of PM and corresponding cost, above data is classified as given below.

To find PM relation between number of Preventive maintenance frequency and cost of preventive maintenance, Regression technique is used with help of Minitab software. Cost of Preventive maintenance includes Labour cost and maintenance cost. The following equation is obtained.

$$C_{pm} = 748.5 + 619.2n - 20.44n^2 \quad [2]$$

Thus by putting value of n=1 to 8 in equation [2] preventive maintenance cost is obtained as follows

Similarly regression analysis is done for number of preventive maintenance and number of replacement. Thus equation [3] show number of replacement (m) and number of preventive replacement (n) using regression in Minitab Software.

$$m = 4.371 - 0.5429n \quad [3]$$

Now put value of n=1 to 8 in equation [3] as shown in table

TABLE V: REPLACEMENT NO (m) AND COST (Cr_j)

No of PM Frequency (n)	No of replacement (m)	Cost of replacement Cr_j=6246*m
1	3.8281	23910.31
2	3.2852	20519.36
3	2.7423	17128.41
4	2.1994	13737.45
5	1.6565	10346.5
6	1.1136	6955.546
7	0.5707	3564.592
8	0.0278	173.6388

Cost of Preventive maintenance and cost of Replacement is calculated as per equation as follows Total cost $f(x)$ = Cost of PM + Cost of Replacement

$$f(x) = \sum_{i=1}^{n} Cpm_i + \sum_{j=1}^{m} Cr_j$$

The main objective is to minimize the total cost thus using interval halving method, the optimize total cost is obtain by solving the example as follow.

TABLE VI: TOTAL COST OF PM AND COST OF REPLACEMENT

PM (n)	Cost of PM (*Cpm*)	Σ(*Cpm*)	Replacement (m)	Cost of Repl. Cr_j	Total cost (*Cpm* + Cr_j)
1	1347.26	1347.26	3.8281	23910.31	25257.57
2	1905.14	3252.4	3.2852	20519.36	23771.76
3	2422.14	5674.54	2.7423	17128.41	22802.95
4	2898.26	8572.8	2.1994	13737.45	22310.25
5	3333.5	11906.3	1.6565	10346.5	22252.8

6	3727.86	15634.16	1.1136	6955.546	22589.71
7	4081.34	19715.5	0.5707	3564.592	23280.09
8	4393.94	24109.44	0.0278	173.6388	24283.08

Consider 'a' as lower bond and 'b' as upper bond, take a= 4 and b=6.
Hence X_m= (a+b)/2; putting values of a & b
X_m= (4+6)/2 , therefore X_m= 5 .
Thus initial interval length L_0=L is calculate as
L_0= L= b-a,
Therefore L_0=L= 6-4=2
Now Calculate $f(X_1)$, $f(X_m)$, & $f(X_2)$ as follows
X_1= a+L/4 & X_2= b-L/4
Thus X_1= 4+(2/4)= 4.5 & X_2= 6-(2/4)=5.5
Now put f(4.5), f(5), f(5.5), in equation [2]
f(4.5) = 3120.99, f(5)= 3333.5 , f(5.5)=3535.79
Now set b= 5 and repeat the procedure until $f(X_1)$ and $f(X_2)$ and are equal.

TABLE VII: OPTIMUM VALUES OF PM AND REPLACEMENT

PM (n)	**Cost of PM (*Cpm*)**	**Σ(*Cpm*)**	**Replace--ment (m)**	**Cost of Repl. Cr_j**	**Total cost ($(Cpm+Cr_j)$**
1	1347.26	1347.26	3.83	23910.31	25257.57
2	1905.14	3252.4	3.29	20519.36	23771.76
3	2422.14	5674.54	2.74	17128.41	22802.95
4	2898.26	8572.8	2.20	13737.45	22310.25
4.5	3120.99	11693.79	1.93	12041.98	23735.77
4.625	3175.076	14868.87	1.86	11618.11	26486.97

IV. RESULT & CONCLUSION:

The research aimed to produce an effective PM model, Considering a maintenance system that consist, number of preventive maintenance (n) and number of replacement (m) activities for a certain period (t) of identical and independent units which are put into use sequentially in time. In order to illustrate the models numerically, and the proposed solution procedure, we captured a representative data set for considered component and it is also useful to mention that for this problem, the optimization models presented above that is total cost F(x) have been solved using Interval halving technique.
The optimized values of Preventive Maintenance (PM) and replacement are 4.5 and 1.93 respectively. The minimum maintenance cost for this frequency is Rs. 23,735/-.

***Abstract*— Vacuum Gripper Design For An Industrial Handling System is a device designed for handling natural stone slabs (graphite slabs). It is a simple pick and place mechanism. The handling task comprises of taking the top slab from a stack of slabs with the help of gripper, transporting it to an unload position via actuators and placing it on that position. Another aim of this paper is to check the deflection (displacement in mm) & factor of safety in the beam at full load conditions and considering all the friction parameters.**

Keywords— Graphite slabs, Gripper, Actuator, Motors, positioning, pick & place mechanism, Factor Of Safety and displacement.

I. INTRODUCTION

This paper explains the overall mechanism of the pick and place process for handling of graphite slabs as shown in figure below. This mechanism is a part of a huge system which is used in processing of graphite slabs in an industry. This paper explains the overall design of mechanism using solid works software for the below given dimensions:

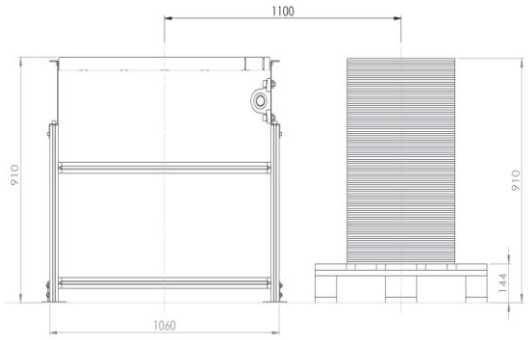

Fig.1. CAD drawing of Actual Mechanism

The dimensions of a slab are:

$W_{max} = 1{,}000\ m$ $\quad H_{min} = 0{,}020\ m$

$H_{max} = 0{,}500\ m$ $\quad T_{min} = 0{,}008\ m$

$T_{max} = 0{,}050\ m$ $\quad W_{min} = 0{,}020\ m$

where, W_{max}, W_{min} are the maximum and minimum widths of the stone slab; H_{max}, H_{min} are the maximum and minimum heights of the stone slab; and, T_{max}, T_{min} are the maximum and minimum thicknesses of the stone slab. The stone slabs are made from granite with density of $\rho = 2700\ kg/m^3$. Design for minimum cycle time for the handling operation. Optimal time (no idle time from the processing machine) $optT_{hc} \leq 4\ s$. According to above specification we have designed the manipulator under the Industrial Automation branch. In this we have considered all the factors like speed, acceleration, frictional resistance due to motion etc.

II. EASE OF USE

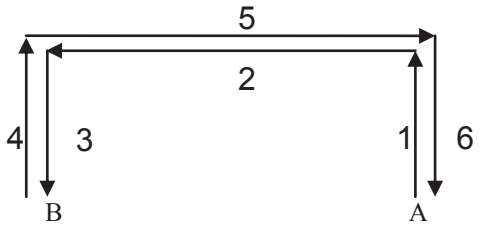

Fig.2-Operational Working

The handling cycle is decomposed to 6 parts (Fig. 3). For every part there are forces that are acting on the handling system. The maximum loading occurs when the system is handling a slab with maximum dimensions as per the assignment. The slab is picked from point A which follows path 1-2-3. Once the slab is placed on desired location B the mechanism follows reverse path 4-5-6.

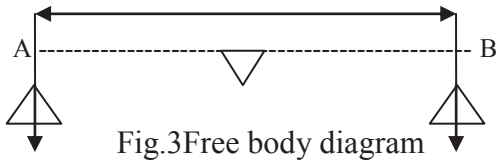

Fig.3Free body diagram

R_A (Reaction at A) R_B (Reaction at B)

The above arrangement shows the actual arrangement of the overall mechanism. In this the whole mechanism is placed on two columns as in the figure. it is the same arrangement as a simply supported beam. The gripper assembly and the sliding mechanism is rested on this simply supported beam.

III. CONSTRUCTION AND WORKING OF MECHANICAL SYSTEM:

The mechanical system consists of following components-

1. Vacuum gripper system
2. Vertical actuator for vertical movement of gripper
3. Guide ways for guiding vertical piston movement
4. Horizontal actuator for horizontal displacement
5. Main supporting frame

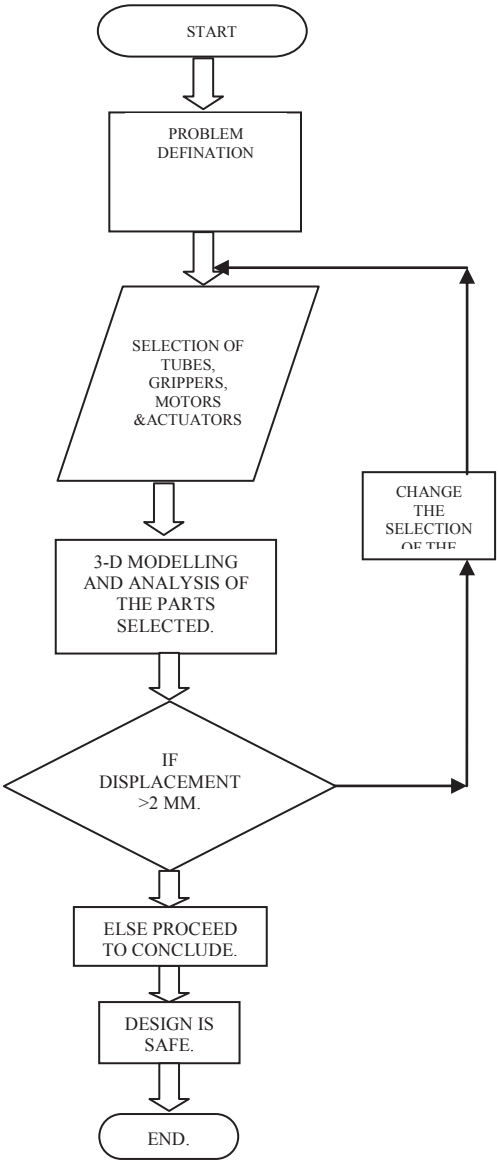
The vacuum gripper system consists of vacuum pads/cups (selected form SMC ZP2_Pads online pdf.), frame for holding the pads and other connecting elements. Here 14 vacuum pads are used as shown in figure for effectively lifting the slab for different conditions. The pads used are bellow vacuum pads. The bellow type pads are used because they do

not impact on the surface to be lifted and any surface irregularities can be effectively handled. The diameter of each vacuum pad is 40mm and material of pad is Urethane Rubber. The vacuum pads hold the slab when vacuum is applied to it and releases the slab as soon as the vacuum is released.

The vertical pneumatic actuator/actuator (selected online form SMC MGP-C_EU actuator for vertical catalogue) is used so as to provide a vertical lift to the vacuum gripper which is holding the slab. This is

required so that the slabs lifted do not slide over each other and damage their surfaces. For this we have assumed the vertical lift to be 50mm.

The load carried by the vertical actuator piston is considerably high. During working it may happen that the dynamic load conditions will tend it to get slightly inclined and this will result in misalignment. To avoid this we provide additional guide ways attached to piston which helps to maintain the perfect vertical movement and also prevents any deformation of piston due to dynamic loading.



Flowchart.1- Process chart.

The horizontal actuator used is mechanically joined rod less actuator (Selected from SMC REA_REB_EU linear actuator for horizontal movement.)with high rigidity and high precision guide type with required stroke of 1100mm. Even this actuator operates on pneumatic power. The rod less piston holds the vertical actuator and gripper system. This horizontal actuator is used for the horizontal displacement of slabs from the pallet to the conveyor. So the sequence of working of different components is as follows-

1. The whole assembly is at position 1 as shown in figure. Now in this position vacuum is applied to the gripper cup. Due to which this slab is lifted.

2. Now the vertical actuator is stimulated and due to pneumatic power supplied the piston of vertical actuator is lifted up. This results in lifting of the slab and gripper system.

3. Now the horizontal pneumatic actuator is actuated so as to give horizontal movement to the rod less piston holding vertical actuator so that position 2 is achieved.

4. Now the vertical actuator is actuated in reverse direction and the gripper system holding the slab is moved downwards.

5. Dampers are attached at the end of the guide ways to avoid jerky operation. Dampers are selected from SMC RB_EU page-5 selecting damper RB 1412.

6. Once the gripper system is brought down the vacuum pressure is released and the slab is dropped on the conveyor.

7. Now the gripper system again moves from here to the original position in reverse order.

8. The above cycle mentioned in points 1 to 6 is repeated a number of times for the required number of jobs.

IV. STUDY PROPERTIES (TABLE-01):

Analysis type	Static
Mesh type	Solid Mesh
Thermal Effect:	On
Thermal option	Include temperature loads
Zero strain temperature	298 Kelvin
Include fluid pressure effects from SolidWorks Flow Simulation	Off
Solver type	FFEPlus
Inplane Effect:	Off
Soft Spring:	Off
Inertial Relief:	Off
Incompatible bonding options	Automatic
Large displacement	Off
Compute free body forces	On
Friction	Off
Use Adaptive Method:	Off
Result folder	SolidWorks document (F:\data0\Assistant\Indiitsi\Model\Gripper)

V. UNITS (TABLE-02)

Unit system:	SI (MKS)
Length/Displacement	mm
Temperature	Kelvin
Angular velocity	Rad/sec
Pressure/Stress	N/m^2

VI. MESH INFORMATION (TABLE-03)

Mesh type	Solid Mesh
Mesher Used:	Standard mesh
Automatic Transition:	Off
Include Mesh Auto Loops:	Off
Jacobian points	4 Points
Element Size	13.0275 mm
Tolerance	0.651373 mm
Mesh Quality	High
Remesh failed parts with incompatible mesh	Off

VII. MESH INFORMATION - DETAILS (TABLE-04)

Total Nodes	78176
Total Elements	40520
Maximum Aspect Ratio	60.083
% of elements with Aspect Ratio < 3	1.31
% of elements with Aspect Ratio > 10	36.4
% of distorted elements(Jacobian)	0
Time to complete mesh(hh;mm;ss):	00:01:18
Computer name:	ADP4124LAPTOP1

VIII. RESULTS:

RESULTANT FORCES (TABLE-05):

Selection set	Units	Sum X	Sum Y	Sum Z	Resultant
Entire Model	N	0.0421467	1423.69	-0.0439034	1423.69

RESULTANT MOMENTS(TABLE-06):

Selection set	Units	Sum X	Sum Y	Sum Z	Resultant
Entire Model	N-m	0	0	0	0

STUDY RESULTS:

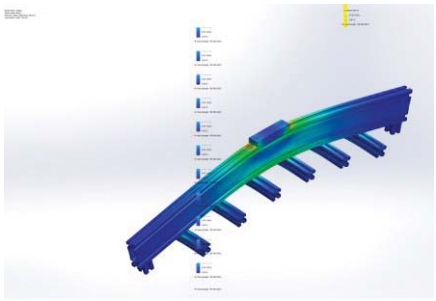


Fig.5- Shows the max deflection in the beam

The modelling and analysis of this overall mechanism is done in Solidworks hence the results indicated in the tables are directly taken from the result document obtained after analysis of the mechanism. As shown in the table the study results prove that the displacement after application of full load and after considering all the factors like friction factor, resistance of air in opposite direction to that of motion of the graphite slab etc, in the gripper holding beam is 0.293065mm which is less. Hence the beam can sustain the load of the graphite slabs effectively in both the conditions like
static & dynamic.

DISPLACEMENT IN MECHANISM (TABLE-07):

Name	Type	Min	Max
Displacement1	URES: Resultant Displacement	0 mm Node: 42	0.293065 mm Node: 44560

IX. MANUAL CALCULATIONS:

QZ= Forces acting in Newton & MY= Moments on points in N-m. Point nos.1,2,3.....7. These are the points of 6 small bars attached on the single beam whose axis are perpendicular to the axis of main beam as shown in fig. 5.

QZ1 = 91.08 N MY0 = +0
QZ2 = 273.63 N MY1 = -7.2864 Nm
QZ3 = 456.18 N MY2= -29.176 Nm
QZ4 = 638.73 N MY3= -65.6712 Nm
QZ5 = -456.19 N MY4 = -91.22 Nm
QZ6 = -273.64 N MY5=-65.6712 Nm

X. CONCLUSION-

From this paper we successfully designed a manipulator assembly for the picking & placing mechanism for graphite slabs for the further operating them for drilling. As stated above, the displacement of beam with full load is 0.293065mm. Since picking and placing is not an critical operation the calculated factor of safety is 5.28848 to 63981.1 (NOTE- FOS is as per Solidworks Results obtained.). This design satisfies the parameters and all the constrains.

***Abstract*— The Artificial Intelligence Automobility (AIA) is designed to make the process of stocking warehouses and material handling in industries safer and more efficient. With current manually operated fork-lifts, employees are at risk of injury. Employers also spend a lot of money on insurance and paying multiple employees to operate fork-lifts in their warehouses. The AIA will limit the need for employees to operate fork-lifts manually. This will not only cut down on long term employer costs but will reduce the chance of injury among employees as well. It takes pallets to and from the docking area and different aisles. The user chooses what they want the fork-lift to do by way of the hand-held user interface. The commands from the user are sent wirelessly to the fork-lift just by one click and the required motion of the fork-lift is achieved. It then drives itself along predetermined paths, picks up the pallet, and brings it to the desired Location. When finished, it returns "Home" where it awaits another command. "Home" is the aisle were the fork-lift parks while waiting for commands; on a full scale electric fork-lift this would also be where it pulls into its charger. For safety purposes, the fork-lift is equipped with a tilt sensor**

(Limit Switches), front and rear proximity sensors, and emergency shut off buttons.

The tilt sensor detects if the fork-lift tips over; if this happens, the fork-lift stops and tells the user via the user control that the fork-lift has tripped over. Once the fork-lift has been righted, the user may then choose to proceed, or go back home. The front and rear proximity sensors detect if an object is in the path of the fork-lift; if this happens, the fork-lift stops and the user control asks the user if it is safe to proceed. Self alignment is the new system allotted to the fork lift in order it will firstly align the job to be picked up and then it will take it to its destination.

Keywords— Artificial Intelligence, material handling, wirelessly, Home sensor, Limit Switches, proximity sensors, tilt sensor, Self alignment.

I. INTRODUCTION (*HEADING 1*)

We the students of Second year Mechanical Engineering are here to present a totally new concept of **ARTIFICIAL INTELLIGENCE AUTOMOBILITY (AIA) ON FORK LIFT MANUFACTURING AND MATERIAL HANDLING**. This Paper brings up a new face of automation world under MECHATRONICS group.

This Paper is fully self imagined and self organized by us in order to provide medium scale as well as large scale industries with some newly implemented technologies in their day to day working. A fork lift usually needs a trained person to handle it with care. But today we will be presenting in front of you a fork lift which won't need any person to handle instead it would work on a remote control(If one fork lift is used) or on computer server basis(If more than One fork-lifts are used).

Basically our aim doing this Paper is to modernize the industrial working and improve its working conditions.

This Paper comprises of some basic concepts of Mechanical Engineering and Electronics and Telecommunication in order to provide automation to the fork-lift system.

A. WORKING PROCESS AFTER AUTOMATION (ON PROTOTYPE):

The main purpose of automation was to enhance the present scenario of the material handling process in industries with a advance technology that will in turn help in increased production and reduced industrial accidents.

This fork-lift can perform all the operations like a normal fork-lift but in an automatic and in advanced form. Some of the operations are stated below-

Automatic lifting. Self-AlignmentTrack detector and self navigator. Obstacle detector and sensing.If in industries when any of the machine operators need the use of fork-lift he has to press the push button provided on his work station. Once the button is pressed via radio frequency signals the nearest fork-lift will reach the Work station, scan the job that is to be loaded via IR sensing. Then the forks will get align according to the scanned job dimensions, and once the alignment is done the forks lift the job and deliver it to its destination. While travelling if any obstacle comes in the way of fork- lift then the proxy sensors sense the obstacle and terminate the further operation.

An automized fork-lift is the one that is implemented with some of the best aspects of Different Engineering Fields.This automation is basically brought into application for a set of fork-lifts (NEARLY 35-40 Fork-lifts) in an industry operated through a strong server. The server will load its program through a computer.

If any defect is noticed by the operator in the server room through cameras, then immediately the workingof the fork-lifts is paused and the defective truck number is entered and is taken aside using a Joystick or even if it is observed that an accident is to happen then the operator can pause the system and can avoid the unexpected The above automations are achieved using MECHANICAL linkages with the help of ELECTRONIC circuits and components.

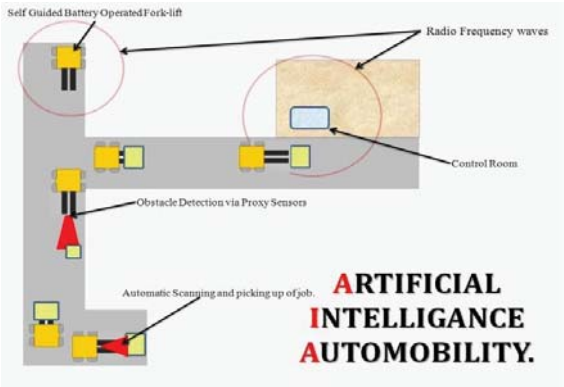

Fig.01 Animated view.

II. TABLE SHOWING COMPARISON BETWEEN MANUAL & AUTOMATED FORK-LIFT

MANULLY OPERATED	FORK LIFT WITH ARTIFICIAL INTELLIGENCE
1. Two persons are required, One trained for driving the truck and other person to guide the driver. Hence many labors are required.	1. It will run on its own with modern technology of self navigation. Only one person is enough to control a group of more than 40 forklifts.
2. The chances of accidents are extremely high in this	2. The accidents won't occur here because of the advancement.
3. We would not get the accuracy required at the shop floor due to manually handling.	3. Here we will attain high accuracy.
4. The person handling the fork-lift may lose control over the path to be travelled leading to instant stopping of work.	4. The self-navigator and track detector will avoid the fork-lift from losing its path thus avoiding the loss of time while doing work.

5. The job cannot be aligned to its perfect scale.	5. Use of sensors will help the fork-lift in aligning the job perfectly.
6. The maintenance for this fork lift is more.	6. It has very low maintenance due to lesser components.
5. The job cannot be aligned to its perfect scale.	5. Use of sensors will help the fork-lift in aligning the job perfectly.
6.The maintenance for this fork lift is more.	6. It has very low maintenance due to lesser components.

.

III. SALIENT FEATURES

1. It is totally automatic hence labour cost is reduced.

2. The sensors used avoid the accidents & its losses when the obstacle comes in.

3. The track detection helps in proper working of fork lift while carrying load.

4. Micro-controller is the one which controls the overall movement of the fork lift.

5. Barcode reader helps in efficient loading and unloading of the products.

6. Auto lift provides high accuracy on the shop floor.

IV. FUTURE SCOPE

1. The user may check the **Video feed** that shows the area immediately in front of the fork-lift and determine if the area is clear.

2. Emergency shutoff buttons are located on three sides of the forklift; in case all other safety options fail, Someone can push one of the buttons which physically disconnects the power to the motors.

3. The fork-lift model can be implemented with Automatic Tyre Changer so that the vehicle can operate in any atmospheric conditions by changing its wheels according to outside atmospheric conditions.

4. Automation on fuel operated forklift which are typically used in core industries the fuel going to be used it will be BIODIESEL.

V. CONCLUSION-

For our Paper, we have concluded successfully that the Artificial Intelligence Automobility installation helps both medium scale and large scale industries in their efficient working. Maintenance required is less as compared to the common fork lift. This advancement helps in improvement of working environment as well as increases the profit of industries by reducing material handling cost. This atomization finally is a boon for nearly all types of companies in and all over the world.

Self –Balancing Platform for Personal Transport

1. Yogesh Risodkar , 2.Ganesh Shirsath, 3.Monali Holkar, 4.Mayur Amle
Electronics & Telecommunication Department, SIEM, Sandip Fondation, Trimbak Road, Post Mahiravani, Nashik, Maharashtra 422213,India

Abstract*— In this paper challenges of transportation of goods and public transportation are well elaborated. The adverse effects are known and well documented. Discussions about various views of the best solutions for these problems are taking place around the world. One of these visions involves the use of advanced technology based on the public transit as the basis for all sustainable solutions. In this search for different methods, MPTDs could help to promote a modal transfer away from the automobile for short-distance trips. Electric scooters and Segways are two user friendly, "in" modes of transportation that facilitate effortless travel and could provide suitable transportation in metro cities. Our aim is to make a design and fabrication of Segway personal transporter. The Segway is based on the principle of inverted pendulum that will keep an angle of zero degrees with vertical at all times. The Segway is an intelligent vehicle which uses gyroscopic sensors to detect the motion of rider, so that it can accelerate, brake or steer the vehicle. This Segway is absolutely ecofriendly mode of transport which causes zero pollution.

Keywords—inverted pendulum; gyroscopic sensors; MPTD; segway.

I. INTRODUCTION

IT is a two-wheeled, self-balancing, battery powered electronic vehicle that maintains its own balance and that of its passenger. It is equipped with a stationary T-shaped control shaft fitted into a platform mounted on two parallel wheels. Segways are driven standing up and handle according to human body dynamics: lean forward to move forward, stand straight up to stop, and lean backward to reverse. For two-wheeled self-balancing robots, stability is vital as they cannot remain upright (balanced) without effort. As previously mentioned, their design concepts are mostly derived from classical robotic research called the inverted pendulum. An inverted pendulum, like its name suggests, is a pendulum that has its mass above its pivot point and not below like traditional pendulums. A self-balancing robot, such as a Segway, is an extended version of an inverted pendulum[1].

One of the most important tasks of autonomous systems of any kind is to be able to acquire knowledge about its environment. This can be done through the use of sensors (Ronald Siegwart et.al 2004). It uses two types of sensors where an accelerometer is an electromechanical device that measures inertial acceleration forces whereas gyroscope is a device used to measure the rate of rotation (angular velocity) of a body. Using microcontroller, the Segway continuously analyses its performance. Five gyroscopes and two sensors work together to determine the Segway's position in relation to its centre of gravity. The onboard computers analyse their measurements and compensate in real time for surface irregularities in order to control the device's movement and ensure the rider's stability[2].

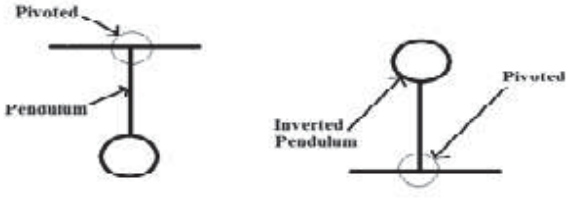

Fig.1.Normal and inverted pendulum

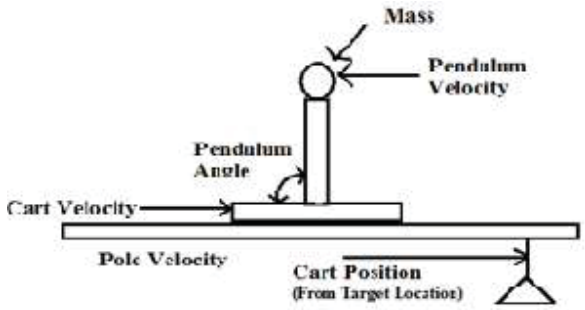

Fig.2.Inverted pendulum experiment set up

II. LITERATURE REVIEW

The United States began regulating Segways in 2002, just after the product began to be marketed and a year after a media campaign promoting the Segway HT and its inventor Dean Kamen. Most defines the Segway as an "electronic self balancing personal vehicle". Few states also resolute to redefine the phenomenon pedestrian to include "a person using a Segway". However, Senate Bill 2004, which defines the Segway as an electric transportation device with a stabilized platform between two parallel wheels, gives states and local authorities the power to pass legislation governing the use of Segways at the regional and local level. It approves the use of Segways on sidewalks under federal authority and on private property[3].

According to the Bill's wording, the device "employs advances in technology and effectiveness to fully and safely integrate the user with personal transportation;enables individuals to travel farther and carry more without use of traditional vehicles," and "promotes gains in utility;minimizes environmental impacts; and facilitates better use of public roadways."[4].

Fig.3. Segway

Segway Human Transporter (HT), which is invented by Dean Kamen, is known as the first two-wheeled, self-balancing system in the literature. Segway HT is demonstrated in fig.3. Also, Segway brings out two wheeled self balancing robotic platform which is called Robotics Mobility Platform (RMP)[5].

Two-wheeled self-balancing systems are mainly classified into two groups as robotic platforms and transporters according to their structure. Robotic platforms are generally constructed as small sized. Fig.4. is that kind of robot. Some of them are driven by an operator while rests are driven autonomously. Fully autonomous robots may also have intelligence. These robots generally have camera in order to detect the environment and path planning[6].

As a transporter system, it is driven semi-autonomously by the driver on it. The driver determines the speed and direction of movement of the vehicle by leaning forward and backward. Most of the transporters are combined of standing base and handlebar which make the driver feel comfortable . Also, steering mechanism is generally mounted on the handlebar.

Fig.4. nBot by David Anderson(Andeson 2007)

The hybrid system is the robot combined with a manipulator. Two wheeled platform is also used for actuator of a humanoid robot. Moreover, a system which is designed as both ground and aerial robot is studied in [7].

Besides the two-wheeled system, similar studies about one-wheeled (unicycle) self balancing system and balancing on ball systems exist in the literature. As a mechatronic system, it is interested by the academicians. Its stability

problem and the interaction among controller algorithm, hardware and software make it popular to study on Segway[8].

Designing controller is the crucial part of the system. The main problem stability is satisfied by the controller. It is designed and implemented . State feedback controller makes the system robust. Observer is used in order to estimate the states[9].

The main sensors of the system are accelerometer and gyroscopes which measure the angle and angular rate of the body, respectively. Most of the studies, use both of these sensors together. All processing are carried out by the embedded controller hardware. Microcontrollers are generally preferred in literature because of affordability . Microcontrollers manufactured by Microchip and Atmel are used in many researches. Digital Signal Processing (DSP) board is used for real time applications[10].

II. PROBLEM STATEMENT

1.Industries working in the field of transportation are required to put more work into building environmental friendly design and construct a fully functional two wheeled balancing vehicle which can be used as a means of transportation for a single person.

2.Design a small footprint electronic vehicle which will promote more environmentally friendly and energy efficient transportation method in metropolitan areas.

DESIGN GOALS

1.Speed should be controlled by the rider leaning forwards and backwards.

2.Turning should be controlled by tilting the handlebar.

3.Balance and transport persons weighing up to 100 kg.

4.Be strong enough to handle minor bumps and going up and down curbs at low speed.

5.Propel the vehicle safely at the maximum speed of 20 km/h.

6.Provide enough torque to balance a 100 kg rider in inclines of 20 degrees.

IV.PROPOSED SYSTEM

A. BLOCK DIAGRAM OF SEGWAY

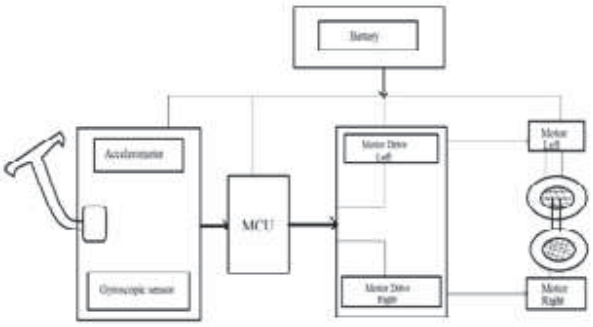

Fig.5. Block diagram

System initially takes the inertial inputs from the IMU (Inertial Measurement Unit) which comprises of the two sensors i.e. a) Accelerometer: A device capable of sensing acceleration. A modern accelerometer often includes a spring loaded structure whose deflection in response to external forces can be capacitively sensed and converted to an electrical signal. b) Gyroscopic sensor: Gyro is used to measure the angular rate of an object with respect to an inertial system.

The accelerometer and gyroscope within the IMU are mounted such that coordinate axes of their sensor are not aligned with self-balancing bot. This is the real fact that the two sensors in the IMU are mounted in two different orientations according to its orientation of the axis need.

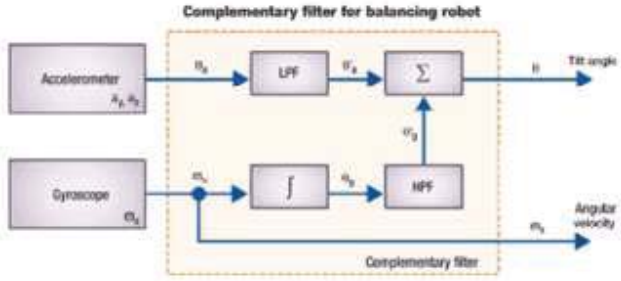

Fig.6. Complementry filter for balancing robot

B. HARDWARE REQUIREMENTS

1.Two wheels to drive the platform.

2.Two motors to drive the wheels.

3.Motor controller unit.

4.Platform to stand on, Gaffer tape and

movement controlling shaft.
5.Batteries to power everything.
6.Sensors to detect leaning.(Gyroscopic and Acelerometer sensor).
7.Electronics to drive the motors.
8.Software to drive the electronics.

C. ALGORITHM

1.Start
2.Acquire the physical parameters using the Inertial Movement Unit.
3.Use Complementary Fusion Technique to detect the corresponding change.
4.If the robot is leaning, drive the wheels in the direction of the lean.
5.If you lean more, go faster.
6.If you lean quickly, go faster.
7.Turns out to be a control systems problem:
  a.Input variable is platform angle.
  b.Output variable is motor speed.
8.By controlling the output variable, attempt to keep the input variable zero.
9.When lean zero with respect to the original vertical positions, stop driving the wheels.
10.Stop

D. FLOWCHART

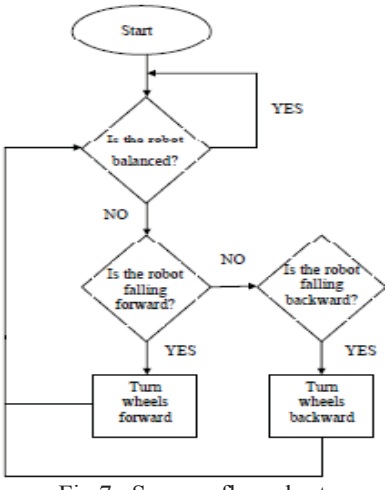

Fig.7. Segway flow chart

V. EXPERIMENTAL ANALYSIS

A complementary filter is a frequency domain filter. At the beginning of this paper it is mentioned that the accelerometer cannot follow tilts at fast motion and that the gyroscope respond better to fast motions. Therefore, this means that for motion that is greater or faster than 0.09 second time period the gyroscope's integrated tilt angle θg is weighted more. When the motion is slower than the 0.09 second time period, the accelerometer tilt measurement θa has more weight than the θg of gyroscope. This technique is chosen over Kalman filter technique because it is not mathematically extensive and simple to implement when programming the microcontroller. s

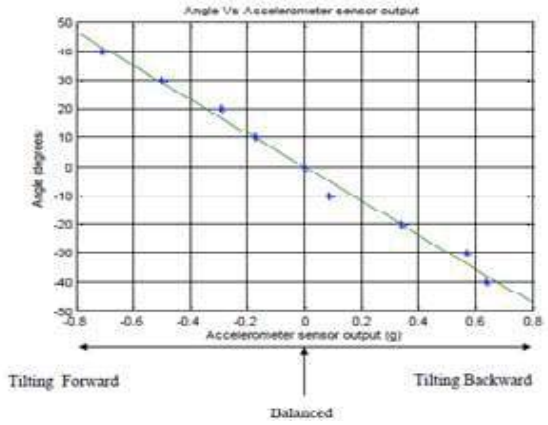

Fig.8. Accelerometer calibration graph

An accelerometer is used in this project to provide the tilt angle that the robot make relative to the balanced position or vertical position. The accelerometer was located at different angle positions along the angle protractor and the sensor output in g-forces and degrees is observed in the serial monitor of the program platform. Then the measured angle from the protractor is compared with the output in the serial monitor.

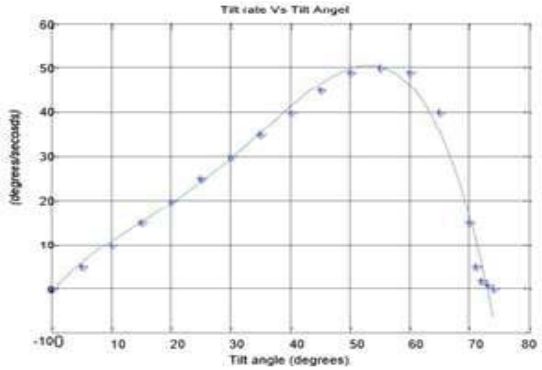

Fig.9. Gyroscope calibration graph

Figure 9 above shows the gyroscope tilt rate against tilt when the robot is made to fall forward from its upright position and caught before it hit the ground. The data is generate in the serial monitor of the Arduino platform then streamed to excel then finally plotted using matlab.

VI. CONCLUSIONS

In this paper the design of personal transporter is presented with more efficient use of energy. Along with the design an alternatives to form an eco-friendly artifice by using the relevant concepts like complementary fusion, PID action, MPTD algorithm are explored. This project is implemented with an idea to find an effective solution to transportation problem. The main objective is to achieve space utilization and minimize the fuel consumption especially for commuting over shortest distance.

From the experimental result it can be concluded that the basic objective of Segway and fuel consumption is satisfied. It is believed that idea implemented in this paper can be beneficial to reduce the future problem in MPTD.

Abstract– **Enterprise Resource Planning (ERP) systems are sophisticated information database that provide an automatic cross –functional business processes. An ERP user, however, often encounters challenges using complex ERP interfaces. Educational ERP implementation has been plagued with failure, but it to be adopted and is expanding in Indian higher education. An AICTE, UGC and others government approving bodies have made ERP system as mandatory software for all technical institutions. Educational ERP system includes almost all related modules. Despite many benefits, ERP users' recognize usability problems and these problems negatively affect the adaptability of the system in large scale. Usability is mainly making systems 'easy to use' and usability testing is a process to collect information about the usability of user interfaces. Usability test consist usability related attributes. Each usability attribute influences a specific characteristic associated with the ERP system. The impact of each usability attribute may very during usability evaluation process. These attributes are navigation, presentation, learnability, customizing, and task support. Usability metrics is generally imprecise, vagueness and ambiguous are characterized by fuzzy aspects and linguistic variables. Fuzzy logic is a branch of mathematics that allows a computer to model the real world the same way that people do. It provides a way to reason with vague, ambiguous and imprecise inputs or knowledge. This paper presents a fuzzy model for assessing the usability of ERP system usability by using these metrics. The present model uses the Mamdani fuzzy Inference approach for developing an overall measure of educational ERP system.**

Keyword–Usability Evaluation Method; Human Computer Interaction; All India Council for Technical Education (AICTE);University Grand Commission (UGC);Enterprise Resource Planning (ERP);Fuzzy Logic.

I. INTRODUCTION

Today, Software is used everywhere. It is a product itself is developed by software developers. To identify which module or part of it is working properly, we require the software testing. Software testing is an essential phase of Software Development Life Cycle (SDLC), whose main task is to provide bugs free and quality software to its users'. According to C.J. Mayers' software testing can be defined as "It is the progression of executing a program or a system by means of aiming of finding errors" [1]. Software testing activities ensures that software has been used is traceable to customer requirements as the software is developed, its GUI (Graphic User Interface) is used as means of user interaction with the software. Initially, software testers start testing its interface to find out its functionality but black box testing methods to detect as many bugs as possible. Software user generally requires a user-friendly interface. Usability is defined [2] as "The extent to which a product can be used by specified users to achieve specific goals with effectiveness, efficiency and satisfaction in a specific context of use". Usability is mainly making systems 'easy to use' and usability testing a process to collect information about the usability of user interfaces. End users always involve as participants of a usability test. It is usually divided into a number of attributes. Usability attributes play a vital role in confirming usability of the system. Usability of software can be understood as how much it is easy or hard for a user to use the software. To make software interface more user-friendly creates complexity in terms of usability and its related attributes.

An ERP is the information system, that an organization adopts to make fast the business process and Indian higher educational institutes are also using ERP system for its routine functions. Different Indian higher educational authorities force the institutes to use the Educational ERP system. Although Educational ERP system integrates many modules to organize educational related data in best ways, still it is always criticized due to complexity. ERP system is more complex only because of cohesiveness and coupling of different business application and process huge data. In spite of tremendous benefits a multifaceted educational ERP system facing usability problems and become less effective as it should be. Usability of educational ERP system can be measure using different usability techniques. Each usability technique has its benefits and drawbacks. We are using the fuzzy model on different usability attributes to find out the user perspective for ERP system. Usability of an ERP system is very important, which is basically a non-functional requirement. Software engineering requirements analysis methods do not focus on non-functional requirements faced resultants a serious problem for software adaptability. Educational ERP system negating non-function requirements are more severe than any functional requirement. Quantification of usability problems of ERP system is desirable for system adaptability. There are various usability models and techniques for assessing ERP system. These techniques aim to predict usability's problems on the bases of hands on experience on the software. Thus, a usability quantitative measurement is an essential part of ERP system. Though available usability literature uses different usability measuring

techniques but as concerned of educational ERP system usability evaluation is very less. The proposed fuzzy model uses various usability attributes and finds the best suitable solution of ERP system usability. In this model, we are using Matlab fuzzy tools for calculating of usability data.

The rest of paper is organized in following sections: Section I discusses introduction part. Section II presents related worked and various currents challenges in Indian Educational ERP system. Section III discusses the factors affecting usability and its attributes. Section IV proposed a fuzzy model. Section V elaborates fuzzy inference approach. Fuzzification process is defined in Section VI. Section VII presents Rule –based for the proposed system. Defuzzification defines in Section VIII. Section IX presents results and discussions of proposed model. Section X presents conclusion and future scope of the paper.

II. Related work

There exist different usability evaluation methods in the literature. One of the widely used methods is a manual evaluation. This method is applicable only when evaluation tool is not available. But, now a day different automatic tools are available for software usability evaluation by using various usability metrics for its evaluation. Metric values of any software can be generated.

Basili et al. in [3] presented the goal oriented data collection method for evaluation of software usability. Goal oriented questions are being formulated to collect the data from the users.

Lee et al in [4] has proposed the common dimension of web usability and verifies the result with the usability metrics. Stolz et al. in [5] used a GPI (Guidance Performance Indicator) to an extent by, which a goal driven web sites achieve its goal. In paper [6, 7] presented information visualization techniques and analyzes data with data mining techniques of website usability.

Kumar et al. [8] presented a fuzzy model for software reliability. Nielsen and Philips in [9] have illustrated inspection based usability techniques while Thmbley in [10] has designed a formal complexity measures for software usability and user experience evaluation. Most of usability evaluation techniques concentrate on isolated specific problems with user interface and widely ignore the overall figure of metrics of usability for a GUI interface of ERP system.

The above literature review, it is clearly observed that previous usability work focused on the certain area of GUI while it is now required to measure user preference and user performance experience on macro level of any software and educational ERP is not an exception from this observation.

III. Factors affecting usability of Educational ERP

Usability is a non-functional requirement, and it is used to measure the characteristics of software product like ease to use, ease of understanding. Jakob Nielson definition of the usability is composed of:

1) Learn ability: How easy is the design for new users' to accomplished basic tasks?
2) Efficiency: How quick cans an experienced user' achieve tasks with design?
3) Memorability: How easily can experienced users get back to the same task after a long period of time?
4) Satisfaction: How pleasant can users' be when they achieve the tasks with the design?

Nielson's and Schneiderman's' proposed different golden rules for usability evaluation. On the basis of these studies, we have selected only most valuable five usability evaluations attributes for our ERP System as follow:

1) Navigation: This attribute is of great important to evaluate the users' experience of the software and also contribute significantly towards usability evaluation.
2) Presentation: This attribute determines the degree of complexity of user interface's layout.
3) Learnability: This attribute focuses to determine required affordance of learning to use the system.
4) Customization: This attribute is used to determine the effort in customizing the system in order to improve the users' performance.
5) Task support: This attribute helps the user with an effective task support to complete a task with an alignment of the system.

IV. Proposed Fuzzy Model

In this paper, we proposed a fuzzy model to predict usability of Educational ERP system as shown in figure1. Input used for this model is usability factors namely Navigation, Presentation, Learnability, Customizing, and Task support and only one output i.e. Usability.

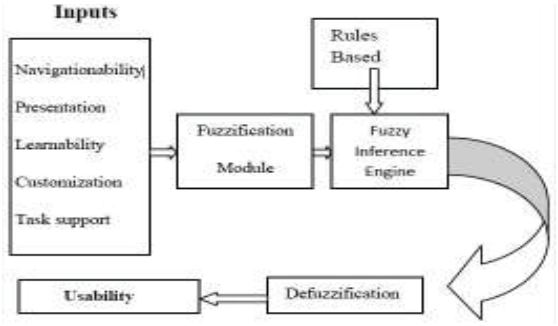

Fig. 1. Block Diagram of Fuzzy Model Predicting Usability

V. Working With Fuzzy Model

The first step is to give the input and determine the degree which they belong to each of the appropriate membership function. Fuzzification block produces the fuzzy inputs by converting the crisp values into fuzzy sets. The fuzzy rule base is a collection of attributes. A membership function associated with given fuzzy set maps as an input value to its appropriate membership function value. Fuzzy inference combines the facts obtained from the fuzzification with rule base and

condition of the fuzzy reasoning process. Fuzzy inference system is a process of formulating a mapping from given inputs to an output using fuzzy logic. Here, we are using the Mamdani fuzzy inference method, which mostly used fuzzy based analysis. Defuzzification block produces the output values to crisp values. The input of defuzzification process is a fuzzy set and the output is a single fuzzy set. Given fuzzy set. the encompasses a range of output values, one need to be returned thereby moving from fuzzy set to crisp output.

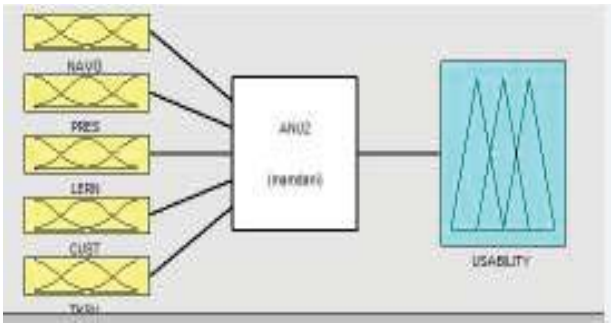

Fig. 2. Structure of Fuzzy Model

VI. FUZZIFICATION

The first step is the fuzzy inference system is to fuzzify inputs. The inputs attribute to the fuzzy system are represented as fuzzy sets. As in fuzzy methodology, the fuzzy set allows its attributes to have a degree of membership. Therefore, attributes of a fuzzy set are represented as a pair of member and degree. A linguistic variable value is used to represent a degree of favor and confidence for membership. The usability parameters Navigation is assumed values for (NAVG), Presentation is assumed values for (PRES), Learnability is assumed values for (LERN), Customizing is assumed values for (CUST), and Task support is assumed values for (TASK), and higher side of resultant value provides the higher level of Usability. All inputs values mentioned as above are defined as a fuzzy number by suitable fuzzy sets. Level of five inputs attributes i.e. Navigation, Presentation, Learn ability, Customizing, and Task support as a fuzzy set are given below:

Navigation = {VBAD, BAD, MODERATE, GOOD, VGOOD}

Presentation = {VLOW, LOW, MED, HIGH, VHIGH}

Learn ability = {LOW, AVG, HIGH}

Customizing = {VLOW, LOW, MED, HIGH, VHIGH}

Task Support = {VBAD, BAD, MODERATE, GOOD, VGOOD}

These fuzzy sets are represented by a membership function. This can be best achieved by deciding numeric range for each of the input and output variables.

TABLE I. FUZZY VARIABLE RANGE FOR NAVIGATION

6-9	GOOD
8-10	VGOOD

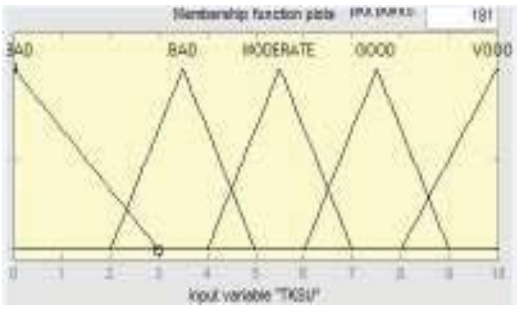

Fig.7. Fuzzification of Input variable Task Support

VII. RULE BASED FOR THE PROPOSED SYSTEM

After fuzzification of inputs, various fuzzy operations are performed to find out the usability of the system. The proposed model integrates the combined effect of NAVG, PRES, LERN,CUST and TASK of usability attributes. On the basis of these attributes, we have defined 150 rules. The sample of rule base is given below:

If (NAVG is MODERATE) and (PRES is LOW) and (LERN is AVG) and (CUST is LOW) and (TASK is MODERATE) then (USABILITY is LOW) (1)

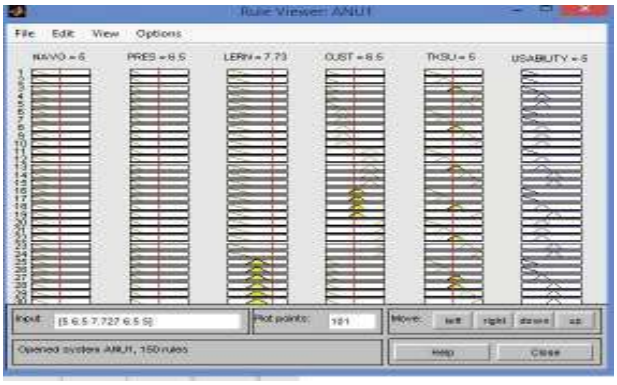

Fig.8 Rule Viewers

VIII. DEFUZZIFICATION

Defuzzification is a process of transformation of output from fuzzy domain to crisp domain. We, de-fuzzified output to get a crisp value to output variable i.e.usability. In this proposed model, we are using a centre of gravity method. In this method, finding is a centre of the area, which determined by joint membership function of fuzzy action. Overlapping area is taken only once, the 3-D surface is to display the resultant of usability variable.

In this, we show two different figures to demo the usability on the basis of rule-based. When Navigation and Presentation are high then Usability is also high for the system. The graphical analysis is shown in three respective figures namely Fig. 9 and Fig.10

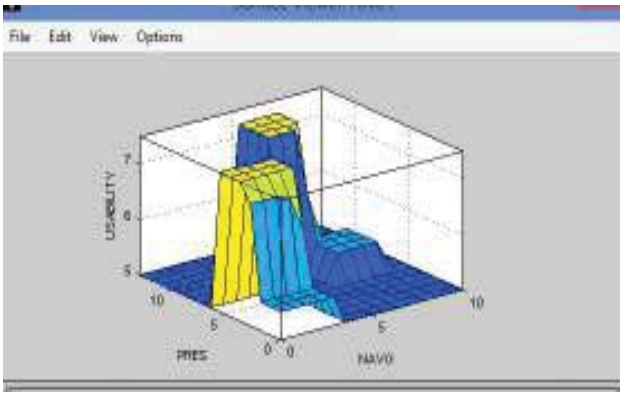

Fig.9. Defuzzification shows the relationship between NAVG and PRES

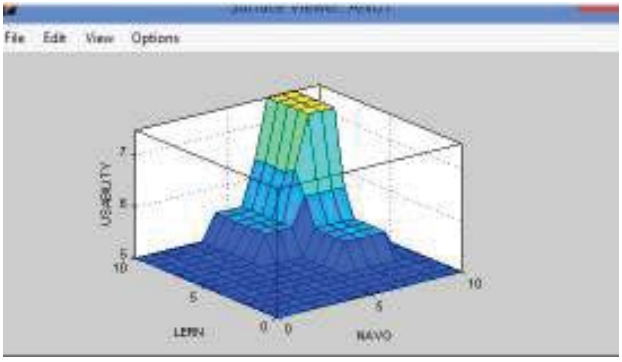

Fig.10. Defuzzification shows the relationship between LERN and NAVG

IX. RESULTS AND DISCUSSION

Suppose we have the following crisp value inputs to the model: NAVG = 5, PRES = 6.5, LERN =5, CUST = 6.5 and TASK = 6.5. These inputs are fed to fuzzification module and after fuzzification of given values the usability of the system is USABILITY = HIGH with membership function. This value has been shown in fig.8. Rule-based viewer. With these inputs values, we find that following rules were fired as given below in Table 6

TABLE 6. EDUCATIONAL ERP SYSTEM USABILITY CALCULATION FOR GIVEN INPUT SET.

NAVG	PRES	LERN	CUST	TASK	USABILITY
GOOD(5)	HIGH(6.5)	AVG(5)	HIGH(5.8)	MODERATE(5)	HIGH(5)

X. CONCLUSION AND FUTURE SCOPE

Many educational ERP systems failed due to low usability. This affects directly the adoptability of ERP system in a higher educational institute. Although, in recent years, various usability evaluation techniques have been proposed by the researchers but none of them quantify the educational ERP system usability using fuzzy model. The final crisp value of usability in this model obtained can help to identify the educational ERP system adoptability by end users'.

In future, data will be collected through online survey of educational ERP system used in Indian institute from its users and various evaluation methods will be applied on above mentioned usability attributes. Then, this fuzzy model will analyze the usability of educational ERP system and designed a new effective usability framework for educational ERP.

ABSTRACT: ***The prediction and optimization of process parameters is an significant aspect in welding process. Therefore, input process parameters play an important role in determining the mechanical properties. Proposed project work aims on optimization of process parameters of bead geometry for Gas Metal Arc welding (GMAW) process. For this study application of the Taguchi approach will be followed by Grey Relational Analysis to optimize the parameters of Gas Metal Arc Welding process for AISI 446 grade of stainless steel plates.***

Keywords—: Bead Geometry, Gas Metal Arc Welding, Grey Relational Analysis, Taguchi Orthogonal Array

I. INTRODUCTION

The Gas metal arc welding processes are quickly replacing the shield arc stick electrode process because the GMAW process can easily applicable to both ferrous and nonferrous metals. GMAW processes are also popular as they can deposit a large quantity of weld metal in a relatively small period of time. GMAW plays a significant role in many industries. Welding is mainly important in heavy fabrication industry, which includes machinery, farming equipment, process tools for manufacturing and mining, and infrastructure for petroleum refining and distribution. During the welding process, input parameters influenced the weldment quality. Therefore, welding becomes as a multi-input multi-output process. To catch the preferred weld superiority in GMAW process it is necessary to study input and output process parameters interrelationships. It is necessary to control shape of weld bead geometry in determining mechanical properties. Therefore, appropriate assortment of process parameter is necessary. It is not easy task to developing mathematical models which gives relationship between input and output process parameters of GMAW process because there were some unknown nonlinear process parameters. Therefore, it is better to resolve this problem by experimental models. In Grey relational generation, the normalized data follows either lower-the-better or larger-the-better criterion according to the selected output parameters. Grey relational grade is to reveal the degree of relation between the defined sequences the reference sequence represents the best process sequence; therefore, higher Grey relational grade means that the corresponding parameter combination is nearer to the optimal. The mean response of the Grey relational grade, its grand mean state may well be calculated from this plot. By using appropriate optimization technique, it gives the optimum parameters setting which can be satisfying the multi-objective problem. The efforts taken out by several researchers are presented in table I.

II. METHODOLOGY

Systematic approach of project work is required to predict and obtain the optimum solution of process parameters and weld bead geometry for GMAW process. This approach consists of the subsequent steps for the proposed work.

A. Identification of process parameters and their levels in GMAW

The process parameters play very significant role to determine the good weld bead. In the proposed work four welding input parameters selected are the welding voltage (V), welding speed (S), wire feed rate (F) and gas flow rate (G) and the output parameters are bead penetration (BP), bead height (BH) and bead width (BW). The weld bead geometry will influence the mechanical properties of the weldment. These are key controllable process parameters and it is required to have minimum three levels of process parameters to expose the true performance of response parameters. Intermediate ranges coded value can be determined by the subsequent equation:

$$x_i = 2(2x-(x_{max}+ x_{min})) / (x_{max}- x_{min}) \quad (1)$$

Where, x_i = the required coded value of a parameter x; x is any parameter value from x_{max} to x_{min};
x_{min} = the lower level of the parameter;
x_{max} = the upper level of the parameter.

B. Development of design matrix

In the proposed work, design matrix based on Taguchi's orthogonal array is selected. Therefore the experiment will be conducted with four controllable, 3-level factors and three performance characteristics. Nine experimental runs based on the orthogonal array L9 (3^4) will be required.

C. Conducting the experiments as per design matrix.

In the proposed work, GMAW machine manufactured by ATE, Pune, INDIA will be used. It is a 3-phase, 50Hz frequency, 300A, forced air cooling semi-automatic machine. The torch is secure to the frame at 90^0 to the work specimen can be kept on trolley which will move at perfect path. Gas

Table1. Summary of literature survey

Ref No	Authors	Year	Process	Process Parameters		Technique Employed	Work Material	Remarks
				Input	Output			
1	M. Sen M. Mukherjee T.K.Pal	2015	DP-GMAW	Current Thermal pulse frequency Arc voltage Pulse frequency	Bead Width Bead Height Bead Depth Aspect Ratio Convexity Index	Response Surface Methodology	Mild Steel	A second order mathematical model was developed to predict the weld bead geometry. Reasonable accuracy found in the weld bead geometry.
2	Pathiyasseril et al.	2014	GMAW	Wire current Welding Speed Welding gun angle Contact tip to work dist. Pinch	Clad Bead Width Bead Height Bead Penetration % of Dilution	PSO-Based Neural Network	IS 2062	The proposed ANN-PSO model is found to be flexible, speedy and accurate than conventional ANN system.
3	Ramos Jaime et al.	2013	Robotic GMAW	Wire Feed Rate Welding Voltage Torch Travel Speed	Bead width Bead height Bead Depth	Radial Basis Function Neural Network	-	In this paper RBF neural network is applied and predicted the weld bead geometry using three level factorial design.
4	Ghalib Thama et al.	2012	GMAW	Weld Current Arc Voltage Weld Speed Wire Extension	fillet bead geometry	Mean Absolute Deviation (MAD)	Carbon steel	This result validates the accuracy and reliability of the calculator to predict the fillet bead geometry and welding parameter for fillet welding in 3F position.
5	Y. T. İÇ, F. ELALDI et al.	2012	GMAW	Current Arc voltage Welding speed	Tension and compression tests of welded joints	Design of Experiment Goal Programming	Armor steel	The developed approach possesses flexibility of adding new constraints, aspiration levels, improvement objectives, and modifying them whenever necessary.
6	S. W. Campbell ElaldiI et al.	2012	GMAW	Voltage Current Travel Speed	Penetration Leg Length Effective Throat	ANN	DH36 grade steel	The output from the model has demonstrated that the use of alternating shielding gases during GMAW results in a step change in the weld metal geometry.
7	M. Aghakhani et al.	2011	GMAW	Wire feed rate Welding voltage Nozzle-to-plate distance Welding speed Gas flow rate	Dilution	Taguchi Method	STEEL ST-37	The wire feed rate has the most significant effect on the weld dilution
8	Fanrong Kong et al.	2011	GMAW (hybrid laser–GMA welding Process)	welding speed	heat distribution and residual stress along the weld joint	3D thermo-elastic–plastic FEM	ASTM A36 carbon steel	The proposed thermo-mechanical FEM could be further applied to the optimization of the processing parameters of hybrid laser–GMA welding as well as other welding techniques
9	Mohammad Mousavi Anzehaee and Mohammad Haeri	2011	GMAW	Droplet size Melting rate	Detaching droplet size Detached droplet size Mean value of droplet detachment frequency	Modified force balance model and the designed estimators	-	A new method to estimate the droplet size in the projected spray mode of a gas metal arc welding process has been proposed which is based on the modified force balance model.

10	Kalenda Mutombo and Madeleine du Toit	2011	GMAW	Arc voltage Welding current Wire feed speed Wire diameter Nozzle to plate distance Travel speed Torch angle Gas flow rate	Corrosion fatigue behavior	Microstructure analysis by Corrosion fatigue testing M/C	Aluminium alloy 6061-T651	The fatigue life of 6061-T651 aluminum in the un-welded condition is significantly reduced on testing in a 3.5% NaCl solution, compared to that measured in ambient air.
11	Her-Yueh Huang	2010	GMAW	Arc voltage Welding current, Welding speed Joint gap	Weld bead geometry Angular distortion Mechanical properties	Taguchi method	AISI 1020 Carbon Steel	The fluxes Fe2O3, SiO2 and MgCO3, not only increased the weld area and weld penetration but also improved the tensile strength and hardness of the GMAW joint.
12	S. Zielin ska et al.	2009	GMAW	Shielding gas, The wire feeding speed The arc current	Precipitates Oxide gangue	Microstructural analysis	Mild steel	These investigations allow to hope a control of the metal transfer mode, taking into account the chemical reactions occurring between melted metal drops and the shielding gas.
13	K. Manikya Kanti and P. Srinivasa Rao	2008	GMA	Thickness of the plate Pulse frequency Wire feed rate, Wire feed rate/travel speed ratio Peak current	bead penetration depth and the convexity index of the bead	Back propagation neural network	--	The results obtained from neural network model are accurate in predicting the weld bead geometry.
14	Erdal Karadeniz et al.	2007	GMAW	Welding current Arc voltage Welding speed	Penetration	The spectrometric analysis	Erdemir 6842 steel	In this study, the effects of various welding parameters on welding penetration in Erdemir 6842 steel having 2.5 mm thickness welded by robotic gas metal arc welding were investigated
15	Davi Sampaio Correia et al.	2005	GMAW	Reference voltage Wire feed rate Welding speed	Deposition efficiency Bead width Depth of penetration Reinforcement	Genetic algorithms and response surface Methodology	Mild steel	It was found that the GA can be a powerful tool in experimental welding optimization, even when the experimenter does not have a model for the process
16	D. S. Correia et al.	2004	GMAW	Reference voltage, Wire feed rate Welding speed	Deposition efficiency Bead width Depth of penetration Reinforcement	Genetic Algorithm	Mild steel	Genetic algorithm had a relatively good quality with no problems of melt-through, porosity or cracks. Considering quality as closeness to defined targets, the genetic algorithm did not manage to achieve all the established targets.
17	I.S. Kim et al.	2003	GMAW	Current Welding voltage Welding speed	Bead width Bead height Penetration	Full factorial design	Mild steel AS 1204	The results obtained show that developed mathematical models can be applied to estimate the effectiveness of process parameters for a given bead geometry, and a change of process parameters affects the bead width and bead height more strongly than penetration relatively.
18	I.S. Kim et al.	2002	GMAW	Layer Current Voltage Welding Speed	Bead height	Neural network	BV-AH32 Steel	The results show that not only the proposed models can predict the bead height with reasonable accuracy and guarantee the uniform weld quality, but also a neural network model could be better than the empirical models

19	Jeongick Lee! and Kiwoan Um	2000	GMAW	Gas flow rate Contact tip to workpiece distance Current Voltage Gap Speed	Width Depth	Multiple regression analysis and artificial neural network	SS41 mild steel	The error rate predicted by the artificial neural network was smaller than that predicted by the multiple regression analysis, in terms of the width and depth of the back-bead.

flow rate can be vary and to be measured by flow meter. The mixture of argon (98%) and oxygen gas (2%) can be used as a shielding gas. The wire feed and welding voltage regulators are provided in the machine to changes the values of same. Variation of welding voltage automatically changes the current. Therefore, four process parameters welding voltage, wire feed rate, welding speed and gas flow rate can be varied in this machine. Based on design matrix, the experimentations are done by varying input parameters. AISI 446 grade stainless steel is used as work-piece material. The stainless steel filler rod of AISI 309L is recommended by American welding society (AWS) will be used for conducting the experiments. To estimate the bead geometry of the stainless steel weldment, specimens having dimension of 150mm x 100mm x 8mm with a single V shaped groove of 30^0 are to be used for each piece as per the design data on the 100 mm side of the plate using vertical milling machine. The land and root gap of 2mm will be provided between the two work pieces.

D. Measurements of the response parameters

The experiments will be conducted by single pass. The samples will be prepared as per American Society of Testing Materials (ASTM) standards and will be cut into three parts for the measurement of bead geometry parameters using water jet cutting machine. The metallurgical polishing process revealed the bead geometry for measuring the BH, BW and BP. The bead geometry parameters will be measured by optical microscope at three places and the average values will be calculated.

E. Analysis of experimental data by Grey-based Taguchi method.

The result obtained for bead width, bead height and bead penetration after experimentation will be first normalized and grey relational coefficients may be evaluated. These Grey relational coefficients for each response will be collected to calculate Grey relational grade. Grey relational grade is the total characteristic of all the features of weld quality. Thus, the multi-objective optimization problem can be transformed into a single comparable objective function optimization problem by the combination of Taguchi approach and Grey relational analysis. Maximum grey relational grade equivalents factor combination to the closer optimal parametric setting.

F. Calculation of S/N ratio

The S/N ratio of overall Grey relational grade can be determined using LB (larger-the-better) criterion by Eq. (2)

$$\text{SN (Larger-the-better)} = -10 \log \left[\frac{1}{n}\sum_{i-1}^{n} \frac{1}{yi^2}\right] \quad (2)$$

Where n = the number of measurements, and yi = the measured characteristic value.

Main effect plot for the S/N ratios can be plotted from the mean response for S/N ratio which gives the optimal parametric combination setting.

G. Confirmation experiment

After assessing the optimal parameter settings, the next stage is prediction and verifies the improvement of quality targets using the optimal parametric combination. The predictable Grey relational grade $\gamma\hat{}$ using the optimal level of

the design parameters can be determined by Eq. (3) and Grey relational grade.

$$\hat{\gamma} = \gamma_m + \sum_{i=1}^{0} (\gamma_i - \gamma_m) \quad (3)$$

S/N ratio for predictable grey relational grade can be calculated using Eq. (2). The Grey relational grade and S/N ratio for initial factor settings, predicted optimal parametric process setting and experimental optimal parametric process setting signifies the comparison of the predicted bead geometry parameters with the original by using the optimal welding conditions; improvement in overall Grey relational grade. This confirms the usefulness of the planned approach in relation to process optimization, where more than one objective has to be fulfilled concurrently. It may be noted that, the Taguchi optimization technique and the optimal parametric combination to be calculated depend on the selected response variables and their individual weight ages.

H. Analysis of variance (ANOVA)

ANOVA is a statistical technique, which can infer some important conclusions based on investigation of the experimental data. If the P-value for a term appears less than 0.05 then it may be concluded that, the effect of the factor is significant on the selected response. Using MINITAB release 15, ANOVA for overall Grey relational grade can be exposed.

III. CONCLUSIONS

From the above literature survey, it is concluded that, only few researchers had attempted the use of Grey relational analysis for the parameters optimization of GMAW process. Very few mathematical models were observed in the literature describing the relation between input and output parameters. Also, the work was not carried on AISI 446. Hence, there is an opportunity for the use of Grey based Taguchi techniques to increase the performance of GMAW process by allowing for various input parameters and trying multi-objective task of the process. Effort can also be made to obtain optimum parameters setting by using Grey based Taguchi technique. It is essential to control the shape of weld bead geometry which plays a significant role in defining mechanical properties as it is affected by weld bead geometry shape.

{abhishek, h2014103018, f2012412, hota}@hyderabad.bits-pilani.ac.in

Abstract — **Delay tolerant networks have not been operated for terrestrial communication on a long term basis. SWiFiIC is an effort to create an extensible platform for future applications in rural communication where delay and loss are less important as compared to cost.**

While costs are minimized, SWiFiIC targets financial sustainability by including a revenue model. As demands for infrastructure increases in rural communication with Internet of things and related applications, SWiFiIC attempts to provide a simple extensible middle-ware which is cost efficient to deploy and operate.

Keywords— Delay Tolerant Networks, Rural Communication, Wireless

I. INTRODUCTION

Delay Tolerant Networks [1] was proposed more than a decade ago with primary applications in deep space communication and other challenged environments like battlefield, underwater communication, deserted locations, post disaster communication etc. Routing and message transfer schemes for DTN are based on store-carry-forward mechanism.

In DTN, there is no end-to-end connectivity between the source and destination nodes. Instead the bundles (DTN messages) are transferred (relayed) from source nodes to other nodes when they have contact. These other nodes (also called intermediate nodes) act as custodians for the bundles. They receive a bundle from a node, physically carry the bundle from one place to another, and pass the bundle to some other node they meet. The latency of a bundle in DTN is unpredictable; it can be of the order of minutes, hours or even days depending on the deployment scenario.

For deep space communications or interplanetary networks, satellites act as custodians of the bundles. DTN has also been attempted for communication with rural communities and remote areas of developed countries [2] or semi-rural areas of developing countries [3]. In rural or remote scenarios people or vehicles moving through the area carry devices that participate in DTN. In such perspective these networks may also be termed as pocket switch networks (with people as carriers) or vehicular ad-hoc networks (with vehicles as custodians).

The author's team, in their prior work have analyzed [4] rural deployments of developing countries. It was noticed that most of the deployment have not sustained themselves without significant external funding. The primary reasons were found to be the complexity of solution and inability of the local community to generate revenue from such solutions.

To mitigate these issues the authors have designed a platform called SWiFiIC (Sustainable Wi-Fi in Indian Context) with focus on **rural** communication in developing countries like India. Over the last three years, the implementation of the design has progressed to a demonstrable proof of concept using open source DTN stack from Braunschweig University of Technology [6].

This paper is a demonstration of SWiFiIC as it exists today and has most of the implementation as proposed in [5]. Extension from [5] is related to change of some notations, usage of screen shots from running applications and discussions on challenges because of central Hub.

Structure of rest of the document is as follows: Section II provides a brief overview of the architecture components. Section III provides details of user interface for management applications. Section IV includes demonstration of a sample application on SWiFiIC. Section V includes details of challenges being observed during SWiFiIC development and deployment. Section VI includes conclusion and a broad overview of future work targeted by the team of authors.

II. ARCHITECTURE

SWiFiIC platform targets four primary goals

- Simplicity of deployment and easy management.
- Usage of "off the shelf components" to benefit from commoditization to achieve cost efficiency and minimize operational cost.
- Commercial model to drive revenue generation.
- Extensible platform with ability to add applications.

To achieve these goals, a deployment of SWiFiIC uses a Linux based hub to control the deployment. All end user devices are Wi-Fi enabled smart phones or tablets. All the

communication uses Wi-Fi (either as Wi-Fi direct or assisted by consumer grade access points).

The platform allows specific applications to have gateway / proxy capabilities extended using the Hub. E.g. broadband connectivity (like NOFN) to the village can be integrated to the Hub. In absence of wired or optical connectivity, 3G/4G can also be used for connectivity. If the cost of communication is a concern, these gateway elements can compress the information. Moreover the platform allows for integration of DTN as a transport for open source frameworks like IoTivity[7].

In this demonstration, the hub is not being used as a gateway for providing Internet based services. It only show-cases the communication within the village.

A. Physical Components

Hub: A low end laptop running Linux (2GB RAM, 250 GB hard disk, dual core). Linux has been chosen primarily to aid debugging during the initial prototyping phase. If needed, it can be moved to an Android device in future. The cost of the device was USD 200.

The software installed on the Hub is Ubuntu 14.04, IBR-DTN, MySQL, Tomcat, PHP and Apache services along with SWiFiIC components.

User terminals: End users have access to SWiFiIC platform using Android devices. All communication relies on Wi-Fi and happens using IBR-DTN service running on these devices. In addition a lightweight SWiFiIC User Terminal Application (SUTA) runs on these devices so that all SWiFiIC applications, list of users and basic billing information etc. can be made available to end users. Extensible applications make use of data provided by SUTA to further implement their functionality. E.g. Messenger gets the list of users.

Operator Terminal: With the intent that Hub need not be physically exposed, an Android device connects to services running on the Hub to provide all management and troubleshooting activities. E.g. User addition and modification, account recharge etc. are provided by the SWiFiIC Operator App (SOA) running on the Operator Terminal. SOA does not rely on DTN, instead it directly communicates with the Hub over HTTP.

B. Logical Components

There are platform specific components called SUTA and SOA. Other than these, SWiFiIC allows third party applications to be developed and deployed on the platform. Each independent App has two components – 1) Android application and 2) Hub specific code. In SWiFiIC paradigm the third party app is called Swilet. The hub component of Swilet is called Hublet, while the corresponding mobile applications are referred to as Moblets.

SUTA Moblet running on end-user device, provides access to the Swilet. As a new Swilet is deployed, the Hublet component automatically runs on the Hub. The details of the new Swilet are pushed (multicast) to all SUTA instances. Once the end user is notified, the end user may decide to install the Moblet piece through SUTA. This functionality is still under development.

Periodically, the SUTA Hublet multicasts the list of users to all SUTA Moblet instances. The SUTA Moblet also responds periodically to these heartbeat messages to provide feedback on round trip delay, node reachability etc. The response includes statistics of device like battery power, software version etc. This information is used by Hublet to update the list of active users and their device details.

The Moblet for other apps can query SUTA for SWiFiIC deployment specific information. Presently this is limited to details of Hub and the list of end-users in the SWiFiIC platform.

C. SWiFiIC communication

Except the SOA, all communication in SWiFiIC relies on unicast or multicast based Delay Tolerant Network. In the present iteration all Moblets talk to their respective Hublets (unicast). The Hublet code may relay or reply in unicast or multicast manner.

As mobile devices come in contact with each other, they exchange the messages so that they reach the destination. Because of reliance on DTN, many DTN bundles may not reach the destination or have significant delay (order of hours). The Swilets need to implement their own logic (like sequencing, acknowledgement, retry etc.) to ensure that it gets the level of quality they desire. Occasionally the end user may need to be notified, especially for people who live on the periphery of the village.

D. Cost and benefit of Centralized Hub

All messages are relayed to the Hub and then distributed back towards the recipients. This approach was necessary to ensure monitoring (and hence billing) of the setup. In future this will also help scan the messages to include IDS/IPS functionality. Further computationally heavy tasks or large storage of data can be delegated to Hublet, thus reducing the space and power needs on mobile devices. Hublets can also act as gateway/proxy to Internet.

Because of such a centralized communication, round trip delays will increase and delivery ratios may drop. In separate ongoing work, authors have done simulations to measure such impact. It was found that in the vicinity of the Hub, congestion sets in as load is increased. To mitigate this, in future design, the team intends to have multiple hubs directly connected over wire.

One benefit that the centralized design allows is the ability to measure quality of service for end users. If the SWiFiIC operator finds that some devices are having poor connectivity, she/he may decide to use dedicated ferry based mechanism to serve such nodes. For example they may hire a person to periodically visit the area where the poorly served nodes reside, or they may allow higher replicas to be created for messages originating or terminating at such nodes.

III. Base Platform Components

SOA and SUTA are two crucial parts of the SWiFiIC platform. Moreover libraries are provided for Hublet and Moblet pieces to simplify development. Figure 1 below captures the deployment for Hub. Figure 2 captures the deployment for typical end user terminal.

A. Hublet basic Logic

For each Swilet, the Hublet needs to implement the handlePayload function. This is the code that gets triggered on receipt of message from Moblets.

Algorithm 1: Handle Payload

function handlePayload(payload, context)
  Identify the *operation* within the payload
  Check account previleges of the originator of payload
  Do the necessary billing for the *operation*
  Invoke the implementation for *operation*
End

handlePayload is the single entry to process all types of operations for the specific Swilet. E.g. for Exam Swilet, it handles operations like, addStudent, sendPaper, submitAnswerScript, getAnswerScripts, getAttendance etc.

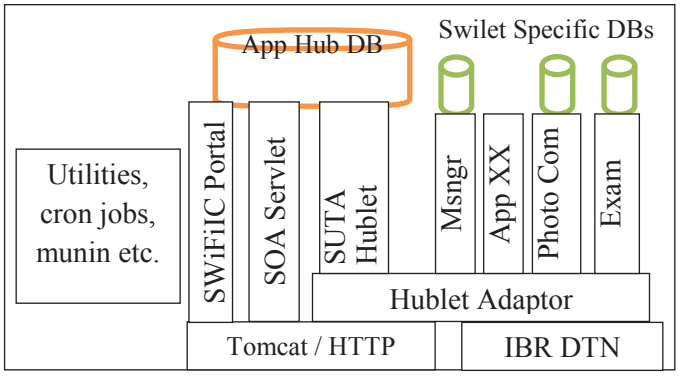

Figure 1 Deployment on Hub

A check on account privilege is necessary to verify the user and avoid impersonation. Billing aspects are optional. The implementation of operation is Swilet specific logic and generally operations such as queries to Swilet specific DBs and generation of DTN messages back towards Moblets.

Hublet code relies on functionality provided by generic code within the Hublet Adaptor so as to mask the complexity of communication.

B. Moblet basic Logic

The Moblet's in present context are Android applications. Other than implementing the logic for the user interaction and application specific requirements, the Moblet's implement a broadcast receiver to handle incoming messages from the Hublet. Further they rely on base libraries (SWiFiIC JAR) to register with the IBR DTN service and to send / receive their messages.

For getting the context of SWiFiIC deployment like Hub's DTN address, list of users etc., Moblets use content provider interface of SUTA.

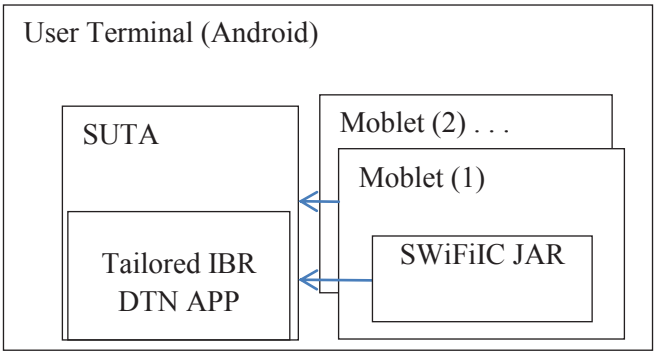

Figure 2 Deployments on User Devices

C. Screen shots

Following figures captures the screen shots for different UI components.

1) SOA

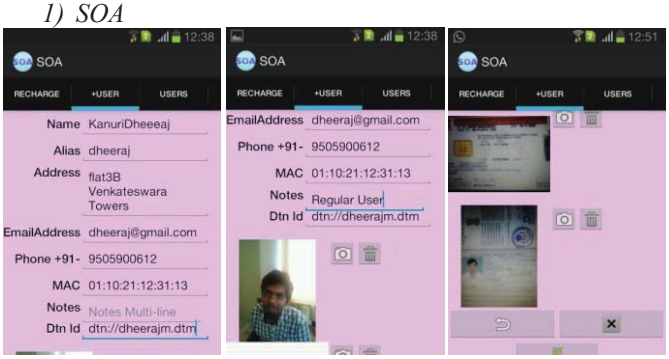

Figure 3 SOA – Add user

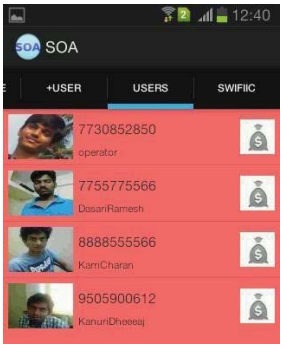

Figure 4 SOA – Other Screens

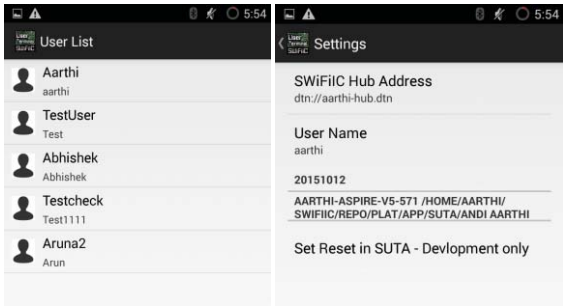

Figure 5 SUTA Moblet

The SUTA Hublet code receives the updates from the Moblets and also generates periodic updates. The figure below captured debug output for some of these scenarios.

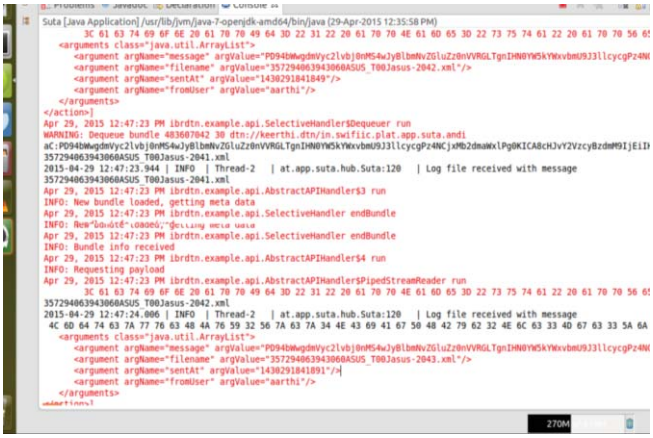

Figure 6 SUTA – Hublet – Node Updates Received

IV. Sample Application

Few applications have been developed to demonstrate the capabilities for the platform. We discuss the messenger app implementation below including a few screen captures.

A. Messenger

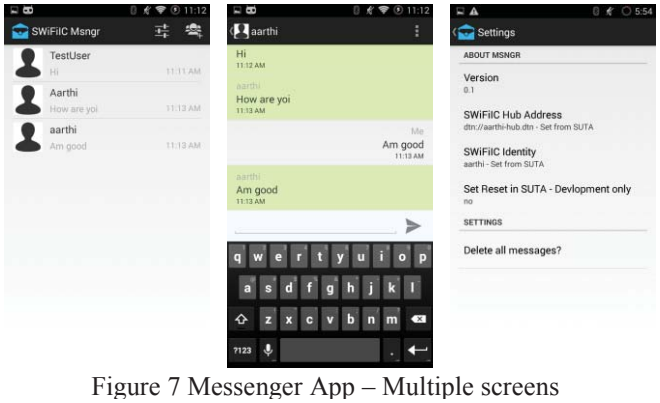

Figure 7 Messenger App – Multiple screens

Hublet: The messenger Hublet after authenticating the sender, debits (notional amount of 1 rupee presently) from their account. Thereafter it queries the DTN id for the receiver of the message and relays the message to the destination DTN node.

Moblet: Majority of the code here is related to UI and tracking of messages received in the past. In addition using the broadcast receiver the code handles incoming DTN messages. To send a new message (towards Hublet) the code uses sendAction on Helper functionality provided by the SWiFiIC JAR files.

V. Development and Deployment Challenges

During the present development and trials for SWiFiIC, it has been noticed that user experience for Wi-Fi Direct is sub optimal. It confuses some of the end users who do not understand the technology in depth.

The peer discovery for IBR-DTN relies on multicast support. In many scenarios for Android devices, the peers have not been discovered even after few minutes. Restarting the Wi-Fi interface or restarting the IBR-DTN service frequently solves this issue. It was also observed that some access points allow peer discovery to happen most of the time, while a few do not.

The author's team has also surveyed a nearby village to better understand the challenges for deployment. While some villagers can afford their own devices, majority of the others still cannot afford to spend four thousand rupees to have their

own tablet. It is an unsolved challenge to create a viable model where the devices can be provided on a subsidized basis, without the fear of loss/theft.

VI. Conclusion and Future Work

SWiFiIC platform is being operated by multiple students within the campus of the authors. It is still far from production ready. Some of the pending items are

- Providing a better way to use Wi-Fi Direct.
- Improving diagnostics and reporting from SUTA.
- Developing other apps.
- Deployment in true rural scenario.
- Multiple Hub with wired connectivity so as to avoid single point of failure and reduce congestion.
- Auditing mechanisms to ensure that the Hublet does not go beyond its manifest.

The authors and the team of students continue to implement further functionality on an ongoing basis. The project code is maintained as open source at www.swifiic.in.

Acknowledgement

The authors are thankful to the development team of IBR-DTN [6]. SWiFiIC platform relies heavily on it. We also appreciate the feedback of reviewers who have helped improve the quality of this work.

Abstract—**Data communication in Wireless Body Area Networks can be used in the vicinity of the human body, among its other applications. Other WBANs using similar frequency bands working in the same vicinity can cause a significant amount of interference to the primary network of interest. This paper presents the analysis of the interference patterns under specific environmental parameters and conditions. Upon analyzing, this paper also suggests an algorithm and based upon it interference mitigation mechanisms to improve the interference scenario in terms of Packet Loss Ratio in WBANs.**

Keywords— Low power Wireless Sensor Network; healthcare; intelligent sensors; Body Area Network; inter-BAN interference; interference mitigation.

I. INTRODUCTION

Body Area Network is a relatively new field of wireless communication as well as remote healthcare. A BAN usually consists of micro sensors implanted inside or on the surface of human body. These sensors can be worn on clothes or worn. The sensors measure different vital parameters such as heart rate, blood pressure, cardio vascular signs, blood sugar etc. The sensors, upon collecting the relevant data, send it to a coordinator node in its network. In this way, coordinator nodes of different body area networks send it to a remotely located computer or a handheld device. It is possible to monitor the conditions of several patients from this central computer at the same time and act according to the values of the respective vital parameters.

BANs are expected to work in a hospital environment and hence, may have to co-exist with other wireless devices working in their proximity and in the same frequency band. This may cause interference. This type of interference can be characterized as Cross Technology Network Interference or CTI, because as the name suggests, different wireless devices using different technologies interfere with each other. For example, in the ISM band (from 2.4GHz to 2.5GHz) there are many sources of CTI available, such as Bluetooth, Wi-Fi, even some of the daily appliances such as microwave ovens, cordless phones etc. These sources can create enough RF interference to result in the deterioration of performance of the BAN of interest. Interference affecting the BAN performance can also occur if two or more networks happen to reside on each other's immediate vicinity. This is characterized as Intra Technology Network Interference (ITI) or Inter-Ban Interference. Furthermore, as per specifications for the IEEE 802.15.6 standard, the performance of a WBAN should remain reliable when upto 10 WBANs are co-located in a 6-by-6-by-6m space [1]. In light of all these considerations for WBANs this work focuses on interference mitigation and hence coexistence enhancement by using simple two-hop, relay-assisted cooperative communications.

The rest of the paper is organized as follows, in section II the related literature to this particular work is discussed. Section III manifests the WBAN architecture that has been used in this scenario. Section IV consists of the contribution of this work and the observations gathered from it. Section V concludes the results of this work.

II. RELATED WORKS

Wireless Body Area Network and interference modelling and analysis is a relatively new topic. Some of the works in this domain includes [2], [3], [4], [5] & [6]. In [2] Z Zhang et al. proposed an interference mitigation mechanism based upon people's social interaction information in social networks. In that particular work, inter WBAN interference is analyzed, social network interactions are detected among WBAN carrying people and then a transmission power game is developed to eradicate interference effects. Rout et al. proposed a mitigation mechanism based on the performance of modifiedand modulated hermite pulses (MHP) for narrowband interference mitigation in the 4.94-4.99 GHz in [3]. W-B Yang et al. proposed interference mitigation using variable data rates, duty cycles and modulation schemes in [4]. Here in [4], the metric of choice to measure interference and improve the interference scenario has been SINR. The proposed algorithm leads to better SINR when compared to its unmitigated scenario and Received Signal Strength Indication (RSSI) would be the most suitable parameter to indicate network performance. In [5], a time hopping code assignment strategy is used to improve Body Area Network performance and a strategy to increase the lifetime of the network is also introduced. Kim et al. proposes a distributed TDMA-based beacon interval shifting scheme to lower the level of interference in BANs in [6]. Here, active period of each BANs coinciding with other networks is avoided through career sensing, thereby reducing the chances of interference.

III. Overview of the System Architecture

A WBAN system can be set up in different ways, and based upon the set up architecture it can be of two types, namely Flat Architecture and Multi Stage Architecture.

In Flat Architecture, usually there are data sensors which collect the data (i.e the vital parameters like heart rate, pulse rate, blood sugar etc.) of a certain patient and relay it to a handheld device or a computer. This computer is comparable to a server computer or a sink node, centrally storing all the data. It is the simpler of the two architectures, shown in figure 1.

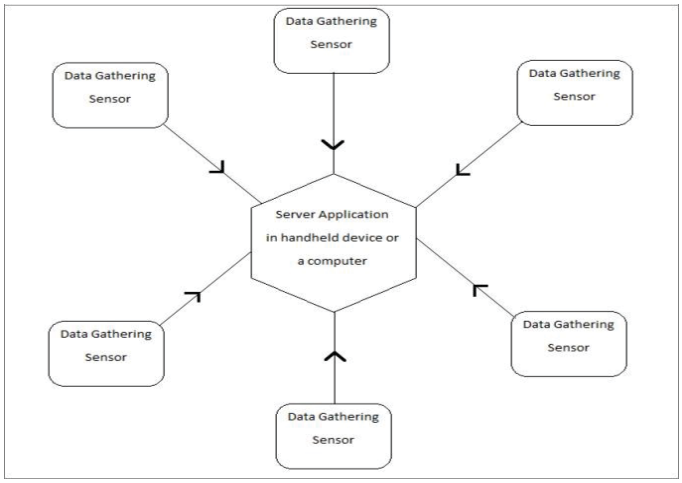

Figure 1: Flat Architecture

In multi stage architecture, devices used are classified into three stages based upon its usage. The Primary Stage is made up of data gathering sensors, which are arranged in clusters. For each cluster, a cluster head node is assigned which acts as a gateway between the server application and data gathering sensors. All the cluster head nodes make up the Secondary Stage. Finally there is the server application which receives all the collected data and this can be called as the Tertiary Stage.

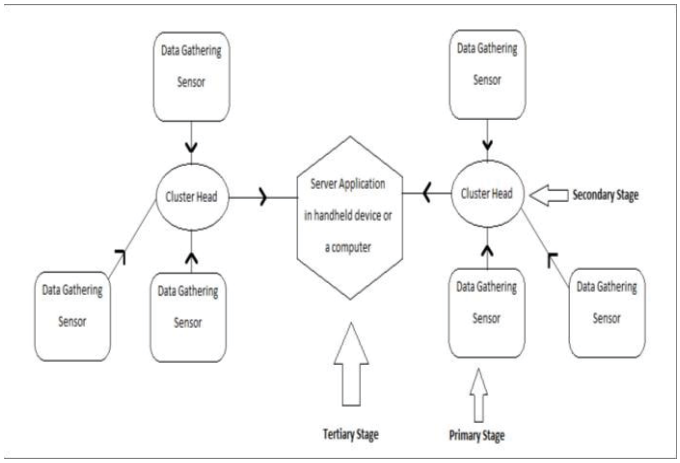

Figure 2: Multi Stage Architecture

In this work, the typical system architecture scenario used for experimentation purposes has been a multi stage architecture using a simple two hop, relay assisted packet delivery mechanism.

IV. System Design

As we have already discussed earlier in this paper, interference affecting WBANs are mainly of two types, such as CTI and ITI. In terms of interference mitigation approaches, there have been a fair amount of interest in CTI mitigation. For one particular instance, Hou et al. in [7] have characterized the effect of non-protocol compliant CTI on BAN reliability and suggested routing and power control strategies to mitigate it. In this work, Inter WBAN interference, also known as ITI has been the focus of the analysis. The mitigation mechanisms that has been proposed here also mitigates the Inter WBAN interference scenario.

A. Experimental Environment

The experimental scenario that has been created in simulator to observe the effects of interference has a few parametric considerations. They are the following,

1) An area of 25 X 20 sqm area is chosen, consisting of 6 WBANs corresponding to six patients.

2) Each WBAN consists of 9 sensors, including one sensor cum cluster head and 8 other sensors to measure vital parameters.

3) A sink node (equivalent to a server application enabled device) is placed in the same environment which receives all the data from the sensor node.

4) The default data rate of the uplink from sensor to cluster head and then to sink node is 250Kbps.The channel is centered at ISM band frequencies (2.405GHz).

5) It is unlikely that there would be many sources inside a hospital room to cause significant amount of path loss. So, the environment created here is a path loss free environment.

The values of the various parameters stated above has been taken after considering practical situations (in hospitals) and typical scenarios used in related similar works [8] [9].

B. Results of Unmitigated Scenario

The software which has been used primarily for all types of simulation regarding multiple Wireless Body Area networks environment is NetSim.

Figure 3 depicts the performance of a typical WBAN in unmitigated scenario working in the system architecture mentioned earlier. Although it is a statistic of one particular WBAN, it can be taken as the representative of typical WBANs. We can make a few observations from here and they are,

A) In a particular BAN, one or two sensor node(s) would be most heavily affected by the interference, while the other nodes in the BAN will perform better. From figure 3. We can assume that node 7 has been most heavily affected by interference and other nodes are less affected in various degrees.

B) The cluster head, receives the packets from sensor nodes, adds its own packets into it and then transmits itinto the server. Essentially it uses a Store and Forward mechanism while sending the packets to the sink node.

C) It is worth noting here that in this scenario, if one particular packet is successfully received without any error and above a pre-defined SINR, then only its corresponding acknowledgement is generated. Otherwise, no acknowledgement is generated.

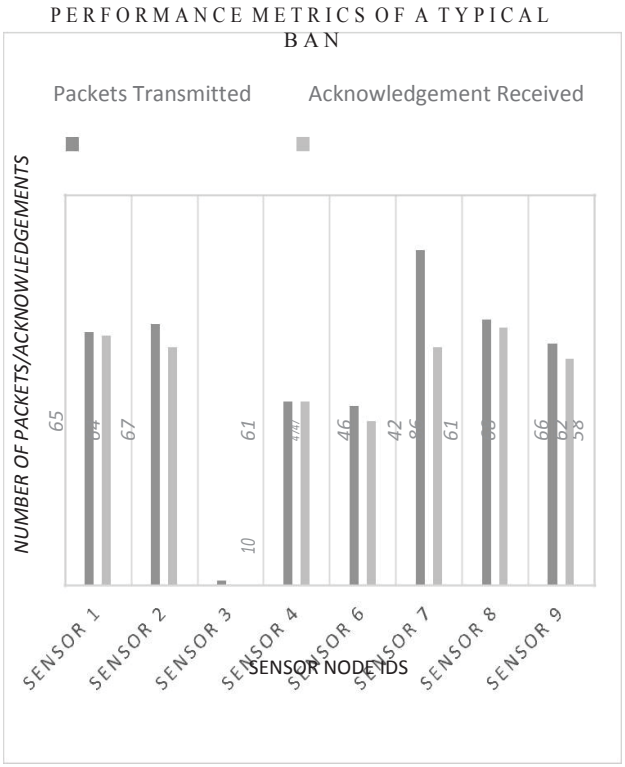

Figure 3: Performance Statistics of a Typical BAN

Table 1: Packet Delivery Statistics of Unmitigated Scenario

C. Observing the Effects of Interference Using File Transfer Model

In the previous section, the quantitative amount of packets collided has been shown, in percentage terms for the sink node and individual sensor nodes. While the statistics are comprehensive, it does not show the extent of the effect of the interference in real time files, which can be sent over these sensors to the sink node, for example ECG signal of a patient. To investigate this particular case, a scenario using four sensor nodes (in 4 X 1 arrangement) which represent a cluster each (containing one node and one node only) was created. ECG signal files are sent by the sensors to the sink node through the same channel (i.e same center frequency). The signal files, after being received by the sink node, has been reconstructed there to get back the sent file. A thorough comparison of the sent file from the sensor and the reconstructed file at the sink node will depict the extent of effect of interference in this scenario.

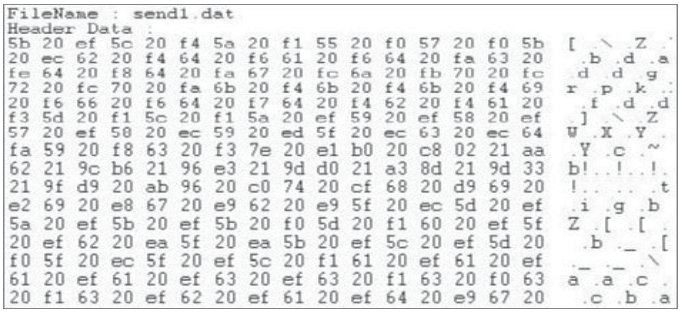

Figure 4: Sent ECG File from Sensor to Sink Node

Figure 4 depicts the sent ECG signal data file from one particular sensor to the sink node, projected in 7 bit ASCII format and converted to hexadecimal representation. At the sink node or server, the PLR in this scenario is approximately 9.09%. Due to this, a certain number of packets have been dropped. The sent file is captured at the sink node and reconstructed there, which is shown in figure 5. It can be argued that the difference between the sent and reconstructed file is obviously due to the packet loss due to unmitigated interference.

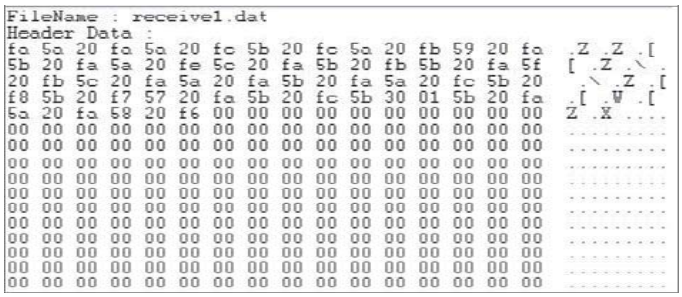

Figure 5: Reconstructed ECG File at Sink Node

D. Implementation of Interference Mitigation Techniques

In this work, two run time interference mitigation techniques are proposed based upon the Packet Loss Ratio (i.e the number of data packets a node has already dropped). Intelligent sensors are used to implement these techniques so that the transmission parameters of individual sensors can be adjusted in run time subject to fulfillment of certain pre-determined criteria. The mitigation techniques are discussed in the following part of this paper.

I. Run Time Adaptive Data Rate in Sensors

Adaptive Data Rate, usually denote the varying data rate of a particular device depending upon fulfillment of certain criteria. In this case, the sensors are having varying data rates with the criteria being the number of packets dropped by a particular sensor node or a cluster head (directly related to PLR). This whole process is carried out in runtime and the adjustment is done automatically by the sensors itself. The criteria upon which these adjustments are done are exclusively user defined so that it can be changed based upon application, environmental parameters or user expectations from the system.

To determine when, how and which data rate is going to be used in the Run Time Adaptive Data Rate mechanism, an algorithm is used. It is given below.

Algorithm: Run Time Adaptive Data Rate

Required: M data rates
Required: $\bar{u}$ (target Packet Loss Ratio)
Initial: u (current Packet Loss Ratio) = 0;
Initial: R_{max}= R1 (default Data Rate);
1. R=R1
2. $\Delta = (R_{max} - R_{min})/ M$;
3. If $u \geq \bar{u} + \delta$ and $R > R_{min}$, then
4. $R = R1 - \Delta$;
5. end if
6. Send Packet;
7. Calculate u;
8. If (Packets != Null), then
9. Go to Step 3;
10. End.

In the given algorithm, δ represents a miniscule amount and represents the step size in data rate used, in Kbps. M is defined as the number of data rate levels to be chosen for the sensor to switch upon, excluding the default data rate level. For example, in this work, 3 different data rates have been chosen to switch upon, namely 200 Kbps, 150 Kbps & 100 Kbps other than the default data rate of 250 Kbps. The range of the data rate values (e.g. from 250 Kbps to 100 Kbps) have been chosen to match the actual data rates used in different healthcare application such as ECG, EEG, and EMG etc. as closely as possible. So, in this case, M comes to be three. It is worth noting that since M, u, $\bar{u}$, R max, R min are all changeable or user defined and can be set in an application specific or user requirements based manner.

Initially, the number of data rate levels (M) and target packet loss ratio ($\bar{u}$) is required from the user. Both of these values are determined based upon hardware & software constraints of the sensor nodes, application in which it is used and required precision in terms of mitigation. The current PLR (u) is set as 0 and maximum data rate (Rmax) is equated to default data rate. The step size is calculated based on Rmax, Rmin and M. As long as the current PLR is lesser than target PLR, packets are sent at default data rate and the resultant current PLR is calculated subsequently during run-time. Now, if this PLR overhauls the target PLR, then the data rate is adjusted by decreasing it by the amount of step size ( ) as long as it is greater than pre-defined minimum data rate. The algorithm ends when the number of packets to be transmitted by a device reaches zero.

The mechanism to choose the data rates and the corresponding number of packet drops (representative of PLR) for each cases is based on optimization techniques. In each of the cases, one data rate and one packet drop ratio is chosen initially on the basis of sensor wise statistic of unmitigated scenario. As we have seen earlier, one or two rogue sensor(s) which perform worse than rest of the sensors in a particular BAN contribute a lot to the PLR of that BAN. So, if we are able to eliminate or decrease significantly the PLR from these rogue sensors, the PLR improves drastically. Primarily, the initial packet drop ratio and data rate chosen for each case is done based upon considerations regarding these rogue sensors. The next step in this mechanism is to optimize the packet drop ratio along with the data rate even more, so that the solution covers higher degrees of packet drops and thereby reducing the PLR. This two-step strategy is followed in every case mentioned, where mitigation mechanism is applied. As we move from Case 1 to Case 5, the packet drop limits for switching to a lower data rate has been made gradually more stringent. In this way, we can arrive at a more robust solution to achieve a better PLR and also compare one particular scheme with respect to its previous one in terms of PLR (as shown in Figure.6).

In this work, test cases to procure observations are obtained using the algorithm. The values of the data rates are grouped along with different target PLRs (represented in absolute number of packets dropped) for the sake of comprehensive observations.

II. Run Time Adaptive Power Level in Sensors

Run Time Adaptive Power Level at the sensors also is an effective mechanism to reduce interference in WBAN. The rationale behind the adaptive power level mechanism is that if a sensor node which is dropping packets switches its transmission power from one particular level to another one, the corresponding interfering nodes will cease to interfere. For example, in the given scenario in this work any sensor node can switch from its basic transmitting power level of 10mW to 20mW or 100mW subject to fulfillment of certain packet loss criteria. In this mechanism, the power levels at which the sensors will switch to for transmitting packets are to be decided by the user. The values of these power levels will have to be chosen after considering certain constraints. These constraints include the permissible SAR values for Body Area Applications, the initial energy and power handling capabilities of the sensors.

E. Results of Mitigated Scenario

As discussed earlier, five different test cases for observation is made by grouping various data rates with packet drop criteria of any sensor node (representing PLR) to examine the results of mitigated scenario. The respective cases are,

I. Default Scenario (250 Kbps data rate throughout)

II. Adaptive Data Rate-I (200 Kbps after 10 Packet Drops, 150 kbps after 30 packet drops by a sensor)

III. Adaptive Data Rate-II (150 Kbps after 8 Packet Drops, 100 Kbps after 15 packet drops by a sensor)

IV. Adaptive Data Rate-III (150 Kbps after 5 Packet Drops, 100 Kbps after 10 packet drops by a sensor)

V. Adaptive Data Rate & Adaptive Power Level (150 Kbps and 20mw of transmitter power after 5 Packet Drops, 100 Kbps and 100mw of transmitter power after 10 Packet Drops by a sensor)

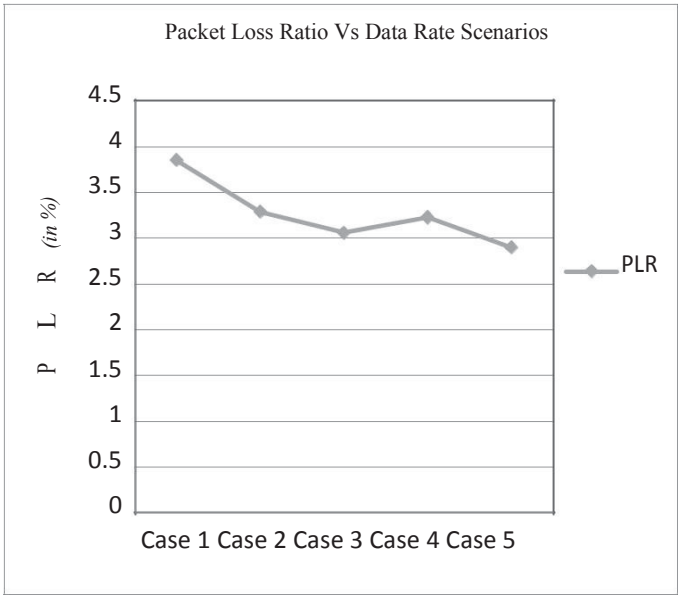

Figure 6: Improvement of PLR vs. different case scenarios

From the figure above, we can infer the comparative effect of the mechanisms on interference. It can be seen that Case2, Case 3 and Case 5 has improved the PLR from its previous scenario, but on the contrary in Case 4, PLR has deteriorated. So, it is clear that an optimization of data rate and threshold metric values are required after extensive implementation, experimentation and observation. In the order the cases has been used, it can be seen that Case 2 is the first bit of interference mitigation mechanism applied on the scenario. So, the improvement of Case-2 (14.77 %, 0.56 % of PLR) over its previous case is highest when compared to improvement of other cases over its immediate previous one. In Case 3, a marginally different and evidently improved mechanism is used. So, essentially it is nothing but an optimization technique. The improvement upon its immediate preceding case here is 9.85%, 0.23% of PLR. Then, in Case 4, the mechanism of Case 3 has been altered to optimize further and it does not improve the Packet Loss Ratio. So, after a certain point, any more change in threshold metric will result in deterioration, it can be observed from here. In this particular case, the deterioration of Packet Loss Ratio is 8.5%, 0.17% of total number of packets sent towards sink node. In Case 5, exclusively the effect of the Run Time Adaptive Power Level scheme has been shown, because while migrating from Case 4 to Case 5 the data rate related metrics are kept exactly the same. This mechanism improves the interference rate by nearly 10 percent, 0.30 % of the PLR. These two mechanisms, Run Time Adaptive Data Rate and Run Time Adaptive Power Level can be used simultaneously to reduce the packet loss rate, in this case by more than 26 percent (Almost 1% of PLR) when compared to normal unmitigated scenario.

V. CONCLUDING REMARKS

In this work, a simulation based scenario is created with respect to practical situations to analyze the patterns of inter WBAN interference, especially in healthcare domain. Furthermore, the impact of inter-WBAN interference is checked on medical signals using File Transfer Model. An interference mitigation mechanism is proposed based on Run Time Adaptive Data Rate algorithm along with a Run Time Adaptive Power Level mitigation mechanism. The mitigation techniques, when used both separately and simultaneously, improve the Packet Loss Ratio and hence the interference scenario. It is expected that the combination of common manual calibration techniques and the mitigation mechanisms would be able to completely eradicate Inter WBAN interference in these scenarios.

Implementation of Low Cost IoT Based Smart Home using Open Source Platform

Varun Tiwari, Avinash Keskar
Department of Electronics and Communication
Visvesvaraya National Institute of Technology Nagpur, India
varun.etrx@gmail.com, agkeskar@ece.vnit.ac.in

***Abstract*— Integration of various devices and sharing of information has been the baseline of improving the human machine interaction. Internet of Things is the concept of connecting the devices to internet for sharing of information. In this work the concept of IoT is used for a home environment. A local network is formed using low cost NRF24L01 transceivers. All the local connected devices send the information to a master node which sends the collected data to the cloud. This cloud data can be accessed from any cloud connected platform. A mobile application can be developed to monitor and control the home remotely. A cloud server provides various applications that can be integrated with the system. This automated smart cloud program enables the home to act smartly under any critical conditions.**

Keywords— Internet of Things (IoT), Human Machine Interaction (HMI), Smart Home, Wireless Sensor Network

I. INTRODUCTION

With the increase in technology every device we use is becoming smarter and intelligent. Every device is designed to interact with the user more conveniently. This design includes integrating the device with sensors so that a lot of information can be known and processed. The more the information the better and smarter the device can be. In order to improve the human machine interaction the information needs to be shared and sharing this information with the user can be done using local network or a global network. Sharing the information through a global network enables the devices to be accessed from anywhere around the world, this concept of connecting various devices to the internet (global network) is referred as Internet of Things (IoT).

A lot of work has been done in the field of home automation, Zhangxing et al. [1] designed and implemented a home monitoring system with local network and computer [2]. Most of the previous work involved a centralized control unit located in the home itself. All the decision and processing were done by this control unit only. But as more and more devices are getting connected with the increase in technology a lot of information is being generated so the architecture of home central computing becomes limited. Instead of a central control unit the information can be send to a cloud server for processing. In this IoT based architecture all the information is collected and is send to the cloud. The cloud can not only receive data from the home but can also receive data of the users. This user data can be the users GPS location which the cloud server can process and find the optimum time to turn on the air condition of the user's room. Thus, this architecture of collecting and processing all the information on cloud improves the HMI.

Reference [3, 4] implements a ZigBee based network architecture. In this work IoT based home architecture is proposed using low cost NRF24L01 modules for forming local network with open source platforms. The next section discusses about the architecture design of the system.

II. ARCHITECTURE

An IoT based home can be designed using different sensing, monitoring and control devices. All these devices can be designed to be connected to internet to share the information. But designing the devices with direct internet connectivity requires more hardware and cost. So in order to reduce the cost of the overall system the devices can be designed to form a local wireless network with one or more master nodes. These master nodes can be designed to connect and share all the collected information to internet. Once the information is available on the internet it can be accessed from any mobile internet platform. Fig.1 represents the structure of the system. Different sensor nodes are connected to the master node within a local wireless network which then connects to the cloud through the master node.

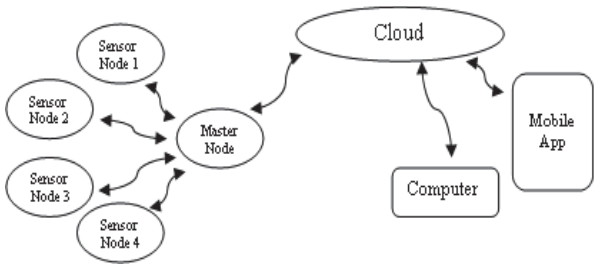

Fig.1 System Architecture

Fig.2 (a) shows the block diagram of a sensor node with one or more sensing/ control/ monitoring unit, wireless transceiver unit, a processing unit and power supply unit. A sensing unit is the interfacing of different sensors to analyze

Fig.3 shows general cloud architecture where a user can create his private secured account. This secured account can only be accessed with API keys, which is known to the cloud account holder only. A secured mobile application can be developed using this API keys to access and control the cloud data. The cloud server has various applications which can be programmed to respond to any critical information coming to the cloud.[5]

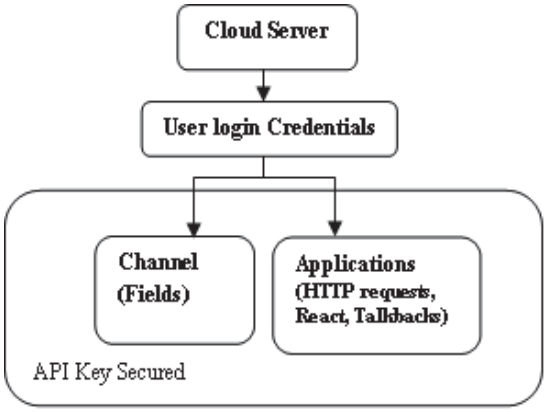

Fig.3 Cloud Architecture

III. IMPLEMENTATION

The complete system can be developed using open source platforms. The design of hardware requires the design of various sensor nodes and master node. The nodes are designed on Arduino open source platform. Atmega328 is used as the microcontroller it has inbuilt 8-channel 10-bit ADC, 23 general purpose I/O pins including 8 ADCs. It has 32KB in system programmable flash memory [6] which provides sufficient space for implementation of our application.

A. Sensor Nodes

Different sensor nodes can be designed to control/ monitor as per requirement. Table 1 shows the different sensor node configuration. Table 2 shows the sensors which can be integrated with the system. A sensor node can be designed to have multiple sensor units and control units. A sensor node should have information sending and receiving capability so the block diagram of the sensor node can be Fig. 2 (a). These sensor nodes use IC NRF24L01 as a transceiver module. It is an ultra low power 2.4GHz based wireless module [7]. It can be configured in a star or tree topology to form a large local wireless network. The nodes can be powered directly through the home power supply with AC to DC converter unit and power regulators. Some nodes which are sensing some critical information such as outdoor sensor or LPG gas leakage sensor can be provided backup power supply with batteries.

The processing unit performs the task of reading the data from the sensors, sending the data to the control units, processing of the data and communicating with the master node. The algorithm for performing the task is explained as follow:

TABLE 1

Environment	Sensor Node
Kitchen	Node with temperature, LPG gas sensor, humidity and exhaust fan control.
Bedroom	Node with temperature, humidity sensor and AC or Lights control.
Garden	Node with humidity, soil moisture sensor, and water pump control.
Outdoor	Node with proximity, Passive infra red sensor, magnetic relay sensor and intruder alarm control.

TABLE 2

Sensor	Modules
Temperature	LM35
Humidity	DHT11(also sense temperature)
Soil Moisture	Analog capacitive rods
Motion Detection	HC-SR510
LPG sensor	MQ6
Proximity sensor	IR-sensor
Door sensor	Magnetic reed relay
Appliance Control	Mechanical / Solid state Relay

Sensor Node Algorithm:

1. Initialize the sensor modules and control units.
2. Initialize and configure the transceiver module to communicate with the master node.
3. Check if any data is received from the master node. If data is received send it to the control unit to perform the operation and repeat step 3 else move to next step.
4. Get the data from the different sensors and process (apply conversions if required).
5. Send the data to the master node.

B. Master Node

A master node can be designed with local network capability and internet connectivity. A master node can receive the data from all sensor nodes and can also send control signals to the sensor nodes. IC NRF24L01 is used for local network connectivity and CC3000 can be used as a Wi-Fi module for internet connectivity. A master node needs to be configured with the addresses of the sensor nodes to form the local network. It sends the information received from the sensor nodes to the cloud so the API keys associated with the users cloud account must be known to the master. The processing unit handles the task of information exchange. The algorithm of a master node is explained as follow:

Master Node Algorithm:

1. Initialize and configure the NRF24L01 transceiver module to communicate with sensor nodes.
2. Initialize the CC3000 Wi-Fi module to connect to the internet.
3. Connect the node to the cloud server with secured user credentials.
4. Check if any data is received from the cloud server, if any control signal is generated then send the control signal to the required sensor node to perform the control task and repeat step 4 else move to next step.
5. Wait and collect the information from the sensor nodes.
6. Arrange the collected information according to the cloud channel and fields.
7. Connect to the cloud server and send the data along with the secured API keys.
8. Check if proper acknowledgement is received, if received correctly move to step 4 else move to step 7.

C. Cloud

A number of cloud servers are available which can be used for the application. The cloud service provided by thingspeak.com is used in this work. A user needs to create a cloud account on the server with proper user credentials. Then the user can create a channel which has different fields that can receive a sensor data. The channel can be made public for free access to anybody or private for secured access. A private channel should be created for secured information sharing. Every private channel generates an API key which can be used for accessing/sending the data from/to the channel. A master node should know this API key in order to send the information to the server. The server also provides various applications that can be programmed as required for e.g. It has an application REACT which can be programmed to automatically turn on the water pump of a garden when the data received from the soil moisture sensor of the garden is below a threshold value. If the API key is known to the user then the information can also be integrated with other mobile platforms through HTTP requests.

IV. Result and Discussion

The complete system has been developed on open source platform. Arduino platform is used for programming the microcontrollers. Arduino Nano is used to keep the design smaller. Open source cloud development platform provided by thingspeak.com is used for cloud application development.The modules used for the design of nodes are low power [6, 7]. For local network formation NRF24L01 module is used which is a low cost device as compared to ZIGBEE Table 3 shows the comparison of the modules. NRF24L01 has high data rate capability and supports star and tree topology which is sufficient for the system even with a large number of nodes. Both are ultra-low power modules. A ZIGBEE can be programmed easily using AT commands and the NRF24L01 needs to be programmed by updating its firmware. The firmware update requires the network configuration with source and destination address settings. The Module can also be configured as a repeater and a number of repeaters can be used to increase the network area.

TABLE 3

Parameter	**ZigBee (ProFLEX01)**	**NRF24L01**
Cost	20$ (approx.)	2$ (approx.)
Range	30m	50m
Power	Ultra Low power device (1uA at standby)	Ultra Low power device (1uA at standby)
Max Data rate	Upto-250Kbps	Upto-2 Mbps
Topology	Star, Tree & Mesh	Star & tree
Interfacing	AT commands	Firmware update

Abstract— **Many reviews on image and video compression and topics related to it have come up in the last decade. However, a review of entropy coding techniques is a subject which has not been touched upon till now. Entropy coding is an integral part of any image or video compression technique entrusted with the task of representing information using minimum number of bits. Although a host of entropy coding techniques are available and are being developed for many applications, this paper compares and analyzes the performance of four major DCT based entropy coding techniques used for image and video compression under two different intra-coding scenarios: i) block based image data compression and ii) image compression using prediction residuals. The DCT based entropy coding techniques being compared are Huffman, CAVLC, Exponential Golomb and Binary Arithmetic (QM) coding. Two image compression frameworks (algorithms) for the two intra-coding scenarios mentioned above are considered for the comparison of these techniques. Entropy coding being a lossless technique, quality metrics such as Compression Ratio (CR) and time required for coding and reconstruction of images are sufficient for performance comparison and evaluation.**

Keywords— Image Compression, Video Compression, Entropy Coding, Huffman Coding, CAVLC, Golomb Coding, Binary Arithmetic Coding, QM coder.

I. INTRODUCTION

The word 'Entropy' means 'uncertainty' or 'unpredictability'. According to information theory, information content or energy contained in an entity is proportional to the uncertainty conveyed by it. That means, the more likely the occurrence of an event, the less the information it conveys. Thus, entropy is used as a measure of the average information content of a symbol or a source. In this sense, entropy coding can simply be defined as a technique for coding entropy of a source or a symbol using minimum number of bits. The basic principle behind entropy coding is that frequently occurring symbols are encoded using lesser number of bits whereas rarely occurring symbols are coded using a longer bit stream.

Many entropy coding techniques have been developed for data compression such as Huffman, Golomb, Arithmetic, EZW, LZW, LZ77, Wyner-Ziv, etc. All of these are not exclusively used for image/video compression. Some are used for text compression, some for compressing speech signals while some may be used for compressing more than one type of data. Besides their classification based on the application in which they are used, entropy coding techniques can be classified as either variable length or fixed length codes depending on the length of the output code words, dictionary based or non-dictionary based depending on the use of look-up table for the generation of code words, prefix or non-prefix codes depending on whether the codes are uniquely decodable or not and so on.

In this paper, we are going to compare and analyze the performance of DCT based entropy coding techniques, namely, Huffman [1], CAVLC [2], Exponential Golomb [3] and Binary Arithmetic (QM) coding [4] and also discuss their characteristic properties in brief. For effective comparison of these techniques, a common framework (algorithm) is developed using the basic image compression scheme in which all the other steps are identical except entropy coding. Hence compression ratio is sufficient to compare the performance of these four entropy coding techniques. Time required is also used as a measure to compare the computational complexity of each of these techniques. Performance of these techniques is also compared using intra-prediction based image compression algorithm using the same two performance metrics.

Outline of the rest of the paper is as follows. Section II gives a survey of the existing reviews related to image and video compression. In section III the four DCT based entropy coding techniques are discussed in brief. Section IV describes the algorithms used for comparison of these entropy coding techniques. Performance comparison results are shown in Section V while conclusion and future work are presented in section VI.

II. LITERATURE SURVEY

Image/video compression and topics related to it have been reviewed many times under different purviews. Most recent ones include a review of several generations of video coding standards by ITU-T and ISO/IEC starting from H.262 to H.265

(HEVC) [5] and a review of the recent video compression standards like H.264 (AVC), H.265 (HEVC) by ITU-T and ISO/IEC and VP9 by Google Inc. [6]. Reviews on different image compression techniques have also been done. One such analysis of the existing fractal image compression techniques have been discussed in [7, 8]. In fractal image compression, blocks of an image are represented using other smaller sized blocks of the same image which are converted into fractal codes. Much advancement has been done in this technique which is well studied and analyzed in [7, 8]. Image compression using codebook vector quantization is another prominent field which is well developed and improved over the years through constant research. [9, 10] have reviewed some of the landmark Vector Quantization (VQ) techniques whereas [11] studies some prominent advancements in image compression using residual VQ. In [9], a survey of different families of VQ such as Spatial VQ, Predictive VQ, Transform VQ, etc. is done. [10], however classifies and surveys different VQ techniques based on the design of their code books. Not only these, there are reviews comparing the performance of the various components of the basic image or video compression schemes. Such as in [12], various reversible integer-to-integer wavelet transforms are evaluated and analyzed from the point of view of image compression and various optimized non-orthogonal transforms for image compression are compared in [13]. Lossy and lossless intra-coding techniques used in image/video compression standards such as HEVC, H.264 (AVC), JPEG2000 and JPEG are evaluated and analyzed in [14]. Thus, this paper focuses mainly on how effectively spatial correlation is used in the mentioned four compression techniques. Also, all the existing block matching based motion estimation and compensation techniques are reviewed in [15]. It is clear from the above discussion that review of entropy coding techniques is a subject which has not been touched upon till now. Specifically, DCT based entropy coding techniques is chosen for review in this paper even though DWT based compression is a hot research topic these days as the performance of DCT based compression algorithms in terms of CR and PSNR is good.

III. Overview of the DCT based Entropy Coding Techniques

Not all the existing entropy coding methods are suitable to be used with the DCT based image compression algorithms. Hence, in this section, the DCT based entropy coding techniques are described in brief.

A. Huffman Coding

Origin of Huffman coding dates back to 1952 [16]. Since then lot of improvements and modifications have been done to it [17-19] with a view to improve its compression performance. Huffman coding is used in the most widely used JPEG image compression standard [4]. But the Huffman coding scheme used in this review is a modified one as proposed in [1].

Huffman coding is based on the principle that smaller code words are assigned to frequently occurring symbols and larger code words are assigned to rarely occurring symbols. Hence, in order to achieve optimal Huffman coding performance, it is necessary that probability distribution of the data source should be known beforehand. Huffman coding procedure creates an optimal code for a set of symbols and probabilities subject to the constraint that the symbols are coded one at a time.

B. Context Adaptive Variable Length Coding (CAVLC)

This is a recently developed technique for H.264/AVC video coding standard. In this scheme, VLC tables for various syntax elements are switched depending on already transmitted syntax elements. Since the VLC tables are designed to match the corresponding conditioned statistics, the entropy coding performance is improved in comparison to schemes using a single VLC table [2]. More detailed information on CAVLC can be found in [20].

C. Exponential Golomb Coding

Golomb codes were first proposed for the representation of non-negative integers, more specifically for the coding of non-negative integer inputs with exponentially decaying probability distribution [17]. Golomb codes offer a host of advantages above Huffman codes. Firstly, they don't require coding tables to provide supplemental information to the encoder. And they can be used to encode a data source with an infinite number of possible symbols [3]. Even though they are defined for encoding non-negative integers, they can be extended to code signed numbers using a suitable mapping function. Use of exponential Golomb coding as an entropy coding technique in a DCT based image compression algorithm is described in detail in [3]. This paper has adopted the [3] version of exponential Golomb coding for comparison.

D. Binary Arithmetic Coding

In arithmetic coding, a sequence of symbols is encoded into a single long code word. Like Huffman coding, for arithmetic coding also source statistics are needed to be known beforehand. Arithmetic coding is useful when coding a source with less number of symbols. Especially when coding a binary source, Huffman may not provide any compression whereas arithmetic is highly efficient in this scenario [21]. Thus, the JBIG format used for coding bi-level images uses arithmetic coding as its entropy coding technique.

Binary arithmetic coding is used as an entropy coding technique in many image or video compression techniques. Apart from its advantages over other entropy coding techniques of encoding a complete sequence of symbols at a time, thereby coding each symbol using non-integer number of bits, it suffers from the disadvantage of having very high computational complexity. This disadvantage was overcome in its adaptive multiplication-free version called Q-coder developed by W. B. Pennebaker and others [22]. QM-coder is an enhancement over Q-coder which is used with some implementations of the JPEG standard [4, 23]. Thus, in this paper QM-coder implementation of binary arithmetic coding is used for comparison.

Properties of these entropy coding techniques can be summarized as shown in Table I below.

TABLE I. COMPARISON OF THE PROPERTIES OF ENTROPY CODING TECHNIQUES

CAVLC	Exp. Golomb	Huffman	Binary Arithmetic
A complete image sub-block is coded at a time.	Only a single coefficient is coded at a time	Only a single coefficient is coded at a time	Bit sequence for the entire image is coded at a time
Variable sized code words	Variable sized code words	Variable sized code words	Single long code word for an input bit sequence
Look –up table required for encoding and decoding	No look-up table required for encoding and decoding	Look –up table required for encoding and decoding	Probability estimation look-up tables required
No need to store length of code words	No need to store length of code words	Length of code words are stored so as to separate code words at the decoder	No need to store length of code words
Encoder complexity is more as compared to decoder	Decoder complexity is more than the encoder	Encoder complexity is much higher as compared to decoder	Both encoder and decoder are complex
Requires more time	Very less time is required	Requires more time	Less time is required

IV. EVALUATION METHODOLOGY

The four entropy coding techniques are compared using the two algorithms shown in fig. 1 and fig. 2 and are discussed below.

A. Algorithm 1

The basic algorithmic framework used for the comparison of the four DCT based entropy coding techniques is shown in fig.1 below. Since, here we are concerned only about the coding gain provided by the entropy coding techniques, all the steps till quantization are same. Identical quantization matrices are used so that coding gain and image quality deterioration due to quantization will be identical in the case of all the four entropy coding techniques. Hence, Compression Ratio and time required for coding and decoding would suffice as performance metrics for comparison of these techniques. Any arbitrary quantization matrices can be used. JPEG quantization matrices resized to size 4×4 are used here. Algorithm 1 can give the comparison of the entropy coding techniques in case of any arbitrary quantization matrix used.

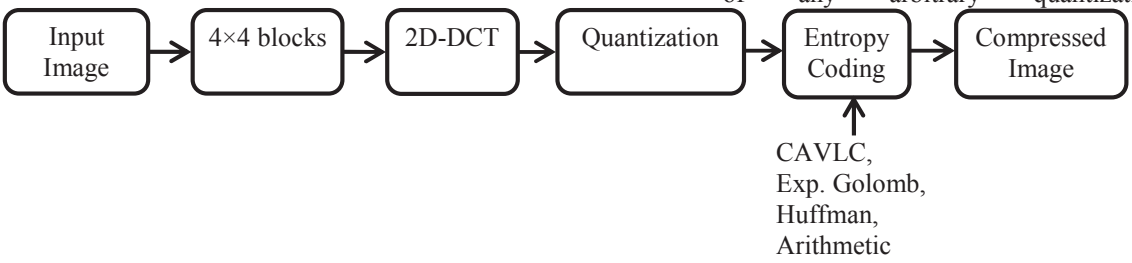

Fig. 1. Algorithm 1 used for comparison of the DCT based entropy coding techniques

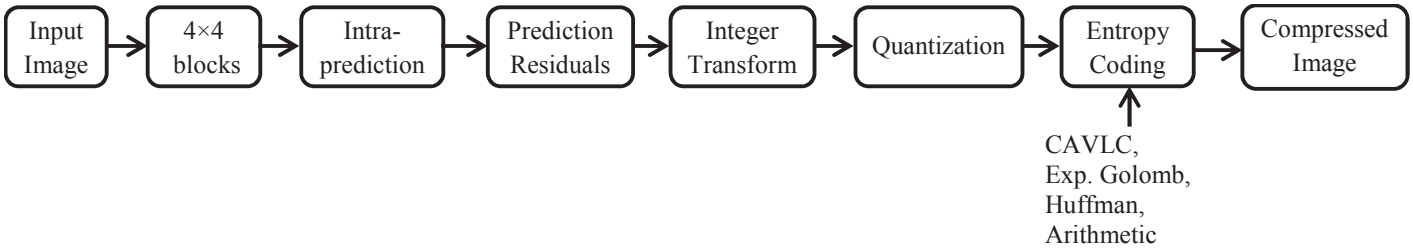

Fig. 2. Algorithm 2 used for comparison of DCT based entropy coding techniques in Intra-prediction framework

B. Algorithm 2

Second scenario considered for the analysis of the entropy coding techniques is the intra-prediction algorithm used to encode I frames in H.264 (AVC). Algorithm for this is shown in fig.2. Originally, CAVLC is used as an entropy coding technique in this algorithm. But in this paper, we have analyzed the compression gain achieved if it is replaced by some other entropy coding technique. DCT based entropy coding techniques can be used in this algorithm instead of CAVLC even though this algorithm uses integer transform as its core transform. This is because integer transform is derived from DCT itself [24]. A Quantization Parameter (QP) needs to be specified to achieve a desired CR and image quality (PSNR). To maintain uniformity of quantization, same QP is used for all four entropy coding techniques. QP of 30 is used for the purpose of comparison which is chosen arbitrarily.

V. PERFORMANCE ANALYSIS

Performance of the DCT based entropy coding techniques mentioned above have been tested on 25 standard test images using the two scenarios discussed in section IV. Parameters used for comparison are CR and time required for coding and reconstruction of an image. PSNR is deliberately not considered due to the fact that entropy coding techniques are

lossless. Hence, PSNR in case of each of the four entropy coding techniques will be same as long as a same quantization matrix in case of algorithm 1 and same QP in case of algorithm 2 is used. Out of these 25 test images, results for 5 images have been tabulated below in Table II and III.

Table II shows the comparison of the four entropy coding techniques using algorithm 1 shown in Fig. 1. From Table II, it can be seen that CAVLC requires maximum time whereas Golomb requires least time. Compression achieved by CAVLC is also very poor as compared to the other three techniques. Arithmetic (QM) gives maximum compression in this algorithm though time required is a bit more as compared to Golomb. Poor performance of CAVLC can be attributed to the fact that CAVLC was developed for entropy coding of the prediction residuals in H.264/AVC video compression system.

Table III shows the Compression Ratio achieved and time required for compression and reconstruction of 5 test images using the intra-prediction algorithm shown in Fig.2 for each of the four DCT based entropy coding techniques. As seen from Table III, CR achieved by CAVLC is the best closely followed by arithmetic coding. But the time required for compression and reconstruction of images using arithmetic is half as compared to CAVLC. Performance of Huffman is worst in terms of compression ratio. Being a non look-up table based technique, Golomb requires least time for compression and reconstruction of these images.

Images for the results tabulated in Tables I and II are shown in fig. 3 (a) to (e). Images reconstructed using the two algorithms are shown in fig. 4 (a) to (e) and fig. 5 (a) to (e) respectively along with the PSNR achieved.

TABLE II. RESULTS OF COMPARISON BY ALGORITHM 1

Image (H×W)	CAVLC		Golomb		Huffman		Arithmetic	
	CR	*Time (sec)*	*CR*	*Time (sec)*	*CR*	*Time (sec)*	*CR*	*Time (sec)*
Image 4 (960×960)	11.52	478.95	20.02	49.59	13.8	318.5	27.02	171.55

Fig. 4. Images reconstructed using algorithm 1

Fig. 4 (a) to (e) show the images reconstructed using algorithm 1 using any of the four entropy coding techniques. This is because, even if entropy coding technique is varied, same quantization matrix is used in case of any of the four entropy coding techniques. Similarly, fig. 5 (a) to (e) show the images reconstructed using any of the four entropy coding techniques as QP used in algorithm 2 is same even if the entropy coding technique used in the algorithm is varied.

(a) Image 4 (PSNR = 36.52 dB) (b) Image 7 (PSNR = 35.57 dB) (c) Image 8 (PSNR = 37.44 dB) (d) Image 14 (PSNR = 35.96 dB) (e) Image 18 (PSNR = 35.07 dB)

Fig. 5. Images reconstructed using algorithm 2

VI. Conclusion and Future Work

In this paper, we have surveyed four different DCT based entropy coding techniques namely, Huffman, Exponential Golomb, Arithmetic and CAVLC. These entropy coding techniques are compared and their performance is evaluated using two different compression scenarios. Although CAVLC performs best in terms of CR in algorithm 2 for image compression using intra-prediction and performance of exponential Golomb is good in terms of both CR and time required for image compression algorithm 1, it is clearly seen that performance of QM coder version of arithmetic coding is optimal under both the scenarios with regard to both CR and time required for compression and decompression of the images. However, choice of an entropy coding algorithm is still application dependent.

Performance of these entropy coding techniques can be analyzed using different block sizes in both the algorithms discussed in this paper and also for increasing QP in algorithm 2. A new hybrid entropy coding technique can be formulated using the discussed entropy coding techniques as a future scope of this paper. Also, some other entropy coding techniques can be modified so as to be effectively used under the discussed scenarios.

***Abstract*— In recent years, cognitive radio technology is emerging for efficient use of spectrum for wireless communications. In this, spectrum is shared between primary and secondary users. Secondary users also called as unlicensed users, makes use of part of spectrum which is not used by primary or licensed users. Hence secondary user systems must be capable of sensing the spectrum and should be able to reconfigure to transmit at different frequencies. For this it must consists of spectrum sensing circuit and a reconfigurable transceiver consisting of reconfigurable antenna. This paper discuss the single module of reconfigurable transceiver which dynamically allocates two different frequencies 2.4GHz and 3.1GHz for transmission. Ultra-wideband patch antenna, Spectrum sensing algorithm and reconfigurable patch antenna are also discussed. The module can be modified to transmit at more frequencies in the range 2.4GHz to 9GHz by having reconfigurable devices such as LNAs, Power amplifiers, Local Oscillators, Mixers etc.**

Keywords*— *Cognitive Radio, Energy Detection Algorithm, Ultra-wideband Patch Antenna, Dynamic Spectrum Allocation, Reconfigurable Antenna, PIFA antenna

I. INTRODUCTION

The electromagnetic radio spectrum access is a limited resource & is regulated by the government agencies all around the world. The current policy is to assign fixed frequency bands to different wireless applications i.e. fixed spectrum allocation policy. At any given time, 15%-85% of the spectrum is unused according to the geographic location. To improve the efficiency, dynamic spectrum access was proposed. Secondary or unlicensed users (SU) may be configured to transmit in the licensed bands without causing any interference to primary users (PU) [1]. Cognitive radios with the ability to adapt transmission parameters according to the environment are perfect fit for the secondary users [2].

In this paper, a novel Cognitive Radio system is proposed consisting of a UWB sensing antenna, reconfigurable transceiver and a reconfigurable antenna in section II. Then a planar micro strip UWB antenna is proposed in section III. Then in section IV spectrum monitoring is done through energy detection with modified threshold selection. In section V the reconfigurable transmitter and receiver is explained. In section VI a reconfigurable PIFA antenna has been proposed.

II. COGNITIVE RADIO SET UP

In this paper a different Cognitive Radio setup has been proposed. The flowchart of the system is shown in Fig 1. Sensing algorithm can be implemented using FPGA or host computer in NI PXI module.

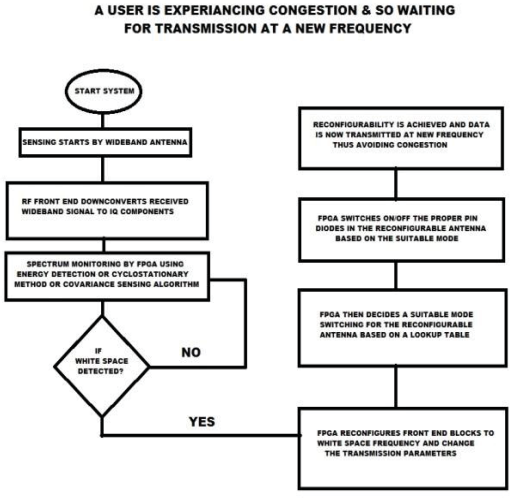

Fig 1. Flowchart of cognitive radio system

III. SENSING ANTENNA

A. Antenna Design Theory

In order to identify unoccupied spectrum bands called as "spectrum holes", an ultra-wideband antenna is required [3]. But designing an antenna giving satisfactory response over an ultra-wideband is quiet challenging. Hence using formulae's given in [4], a narrowband patch antenna is designed and then certain techniques are employed to widen its bandwidth. A rectangular patch antenna was designed and simulated using Ansoft's HFSS software (14.0). An inset feed technique is used to feed the patch for 50Ω impedance matching. An infinite ground plane is used so that maximum radiation goes into the broadside direction to get a directional radiation pattern. The simulated return loss is found to be -14.7dB at 2.4GHz. Bandwidth of patch is 83.6MHz.

The first change in achieving the wideband response is to use elliptical shape patch rather than rectangular [5]. Inset feed is removed in order to radiate patch in multiple resonant frequencies. Ground plane is made finite so that it supports multiple resonating modes. Overlapping closely spaced multiple resonant modes can achieve wide bandwidth and this is the idea of obtaining the UWB bandwidth.

The width of ground plane is determined using the parametric analysis and its optimum value is found to be 10.82mm. The gap between ground plane and patch controls the coupling of fields. This coupling causes to spread the impedance bandwidth and hence must be accurately measured using parametric analysis [6]. The optimum value of this gap is 0.9mm.A slot in ground plane is inserted in order to get better frequency response at these frequencies. The slot is optimized for its dimensions. Also current distribution of patch is studied and a rectangular slot was inserted at the place where it was minimum and its optimum dimension is decided using parametric analysis which comes to be 3.53mm*18.5mm.

B. Final Design of ultra-wideband antenna

Table 1 provides dimension of the whole geometry.

Table 1. Dimensions for ultra wideband patch antenna

Objects in Antenna	Dimensions (mm)
Substrate	45*45
Patch	29.44*38
Micro strip line	3*12
Rectangular slot in Ground	1.6*5.1
Rectangular slot in Patch	6*18.5

The gain of narrowband patch when it was radiating at 2.4GHz was found as 3.1342dB and had directional radiation pattern, Whereas the proposed UWB antenna is having gain of 3.54dB at 3.8GHz and omnidirectional radiation pattern. This gain value is acceptable in UWB communication and cognitive radio applications. Ultra Wide band antenna was fabricated with substrate as FR4 epoxy. Fig 2 shows the fabricated antenna with finite ground plane and rectangular slot in patch and ground. The antennas were connected through SMA connector. Starting frequency of 1GHz and stop frequency of 15GHz were chosen.

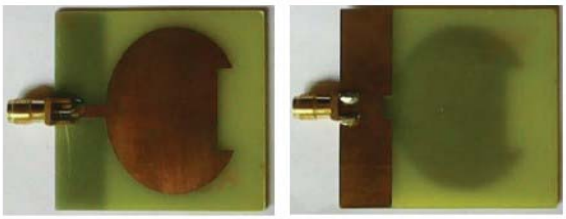

Fig 2. Fabricated antenna: top view (showing patch) and ground plane

IV. SENSING ALGORITHM

A. Algorithm

Energy detection, matched filter detection and cyclo stationary feature detection are important spectrum sensing methods. An energy detector can be implemented by averaging frequency bins of a FFT. Increasing FFT size N improves frequency resolution which helps narrowband signal detection [7]. Longer averaging time reduces the noise power thus improves SNR. This is followed by threshold detection. If noise power is known, threshold can be set based on noise power. The proposed energy detection do not need any prior knowledge of the noise [8].Let us assume that the received signal has the following simple form

$$y(n) = s(n) + w(n) \quad (1)$$

where s (n) is the signal to be detected, w(n) is the additive white Gaussian noise (AWGN) sample, and n is the sample index. Note that s(n) = 0 when there is no transmission by primary user. The decision metric for the energy detector can be written as

$$M = \Sigma_{n=0}^{N} |y(n)|^2 \quad (2)$$

where N is the size of the observation vector. The decision on the occupancy of a band can be obtained by comparing the decision metric M against a fixed threshold λ_E . This is equivalent to distinguishing between the following two hypotheses:

$$H_0: y(n) = w(n) \quad (3)$$

$$H_1: y(n) = s(n) + w(n) \quad (4)$$

The white noise can be modeled as a zero-mean Gaussian random variable with variance σ_W^2, i.e. $w(n) = N(0, \sigma_W^2)$. For a simplified analysis, let us model the signal term as a zero-mean Gaussian variable as well, i.e. $s(n) = N(0, \sigma_s^2)$. The model for $s(n)$ is more complicated as fading should also be considered [9]. The performance of the detection algorithm can be summarized with two probabilities: probability of detection $P_D$and probability of false alarmP_F. P_D is the probability of

detecting a signal on the considered frequency when it truly is present. It can be formulated as

$$P_D = P_r(M > \lambda_E | H_1) \quad (5)$$

P_F is the probability that the test incorrectly decides that the considered frequency is occupied when it actually is not, and it can be written as

$$P_F = P_r(M > \lambda_E | H_0) \quad (6)$$

The mean value, variance and the peak value of received signal, y(n) is computed. Then the following condition is checked at every frequency bins of FFT.

Peak value of y(n) - mean of y(n) > P_F * variance of y(n) (7)

If this condition is satisfied then a signal is detected and the corresponding carrier frequency is estimated. The decision threshold $\lambda_E$can be selected for finding an optimum balance between P_D and P_F . When PF is high, probability of success is also high. This method uses only incoming data and no other prior information of channel noise is needed.

B. Hardware setup

The hardware demonstration consists of generating a QAM signal of certain carrier frequency and transmitting using an antenna. It is then received using the UWB antenna along with the noise. The spectrum sensing is performed on this received signal by energy detection algorithm. After spectrum sensing, the carrier frequency of the received signal is estimated and verified as the transmitted carrier QAM frequency. NI PXI and NI VST 5644R along with UWB antenna is shown in Fig. 4. This is capable of sensing any signal from 65MHz to 6GHz.

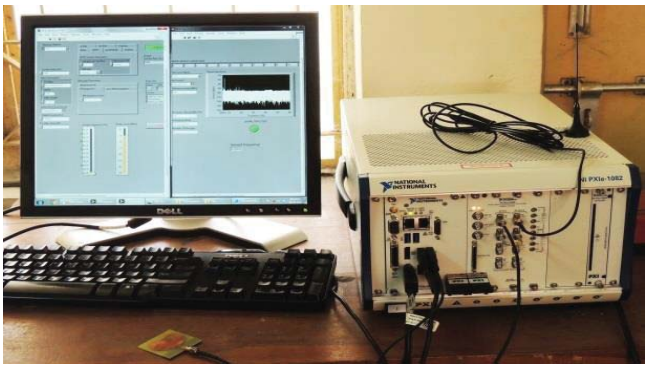

Fig 4. Spectrum monitoring using NI PXI and NI VST with UWB antenna

V. RECONFIGURABLE RF TRANSCEIVER

A. Design and simulation of RF transceiver

Cognitive radios are adaptive and programmable systems which know users preferences and automatically adjust to changes in the operating environment [10]. Before feeding to baseband processor such as FPGA or host processor, signal received through wideband antenna is processed by a re- configurable transceiver so as to down convert the signal. Receiver section is used for sensing as well as data receiving purposes by means of switching. Mode selection in reconfigurable operation is achieved mainly by filter bank and mixer sections.

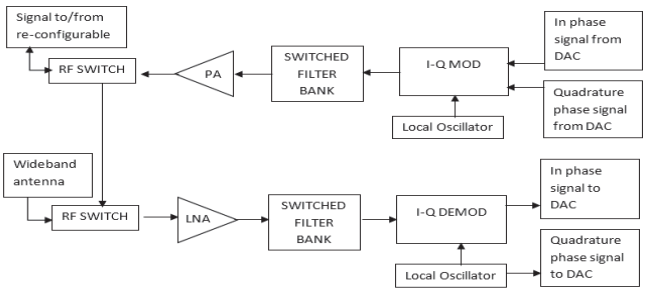

Fig 5. Reconfigurable transceiver block diagram

In order to understand the basic operation and optimization of receiver components the system is first simulated using the software Agilent ADS. Switches are manually controlled for the frequency selection.

Cognitive radio front end has a sensing part along with the reconfigurable section. Sensing network will sense the spectrum; in this case it senses the two bands i.e. 2.4GHz and 3.1GHz.and checks the output signal level. This output signal is used to trigger the control voltage of re configurable part. Sensing part always senses the spectrum to find the spectrum holes in these two frequencies. Once the vacant frequency is found the reconfigurable system will tune itself to that particular frequency. Hence sensing part will act as a control unit of re configurable section. Output of sensing network is given for energy detection and then accordingly control action takes place. The output of sensing circuit is used to drive a switch which decides the operating frequency of reconfigurable section [11]. For a control voltage of 1 V the sensing antenna is designed to be operated at 3.1 GHz and checks whether output level is high or not. If the signal level is high then the device will be re configured to 2.4 GHz. Separate IF frequencies are deliberately given to each user so as to distinguish them. 100MHz is set for 2.4 GHz user and 50 MHz for 3.1 GHz is assigned.

B. Hardware Emulation

Reconfigurable transceiver is designed by integrating different components of Analog devices and Mini-circuits. Direct conversion transceiver architecture is employed for the simplicity [12]. Individual characterization of each component is carried out using vector network analyzer, N5230A PNA (Agilent technologies), and then system design and verification is carried out. Other devices used for the verification process are E4407B Spectrum analyzer and E8267D Vector signal generator (Agilent technologies).

RF signal from signal generator which acts as the primary user signal is transmitted and a spanner shaped UWB antenna is used for receiving purpose. Output of antenna is connected to wide band LNA followed by the band pass filters. Local oscillator frequency is programmed according to the input signal frequency. ADF 4351 IC of analog devices is used as Local oscillator which is one of the main components responsible for reconfiguration. It generates signals from 400MHz to 4.4 GHz and is also programmable. Manual configuration is carried out in this work. USB port connected to the device ensures power supply as well as software interface.

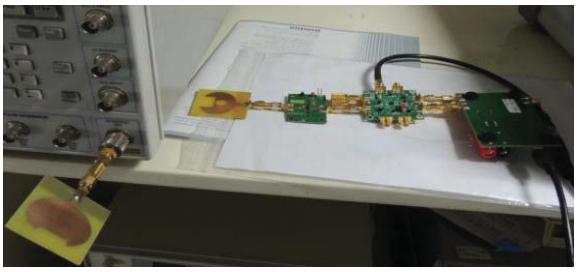

Fig 6. Reconfigurable receiver setup

When the input signal is of 2.4GHz the frequency synthesizer will be tuned to 2.6GHz resulting an IF frequency of 200MHz. Similarly for 3.1 GHz user, local oscillator is set to 3.4GHz to get an IF frequency of 300MHz. Different IF frequencies is given to distinguish between the users. IF signal is demodulated using IC ADL5380. I and Q components are fed to NI PXI module. The processing can be done either by host computer or FPGA inside NI PXI.

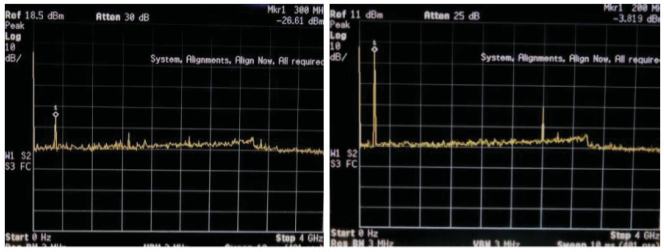

Fig 7. Output spectrum of received signal at 300MHz and 200MHz IF

If primary signal is detected, the transmitter must start transmitting at a new frequency. The transmitter circuit should be reconfigured at a new transmitting frequency by controlling LO frequency using software and changing the antenna mode in reconfigurable antenna. The mode in reconfigurable antenna can be changed by changing the switch configuration obtained from Digital I/O pins of NI VST module connected to NI PXI. The required switch configuration is estimated with the help of lookup table loaded inside the code in NI VST module. In phase and quadrature signal from the source is modulated and is transmitted using the reconfigurable antenna in this section. The transmitting secondary user signal can be generated inside an FPGA or host computer and passed on to reconfigurable transmitter stage. In this case signal demodulated by ADL5380 is given as I and Q input of modulator IC, ADL 5375-15. Output signal is then filtered and amplified by power amplifier.

Fig 8. Reconfigurable transmitter setup

The signal from processor or FPGA is normally in the form of in phase and quadrature component. So this signal is first modulated by wideband modulator IC ADL 5375-15. Tunable frequency synthesizer provides the local oscillator frequencies corresponding to each user. Wideband power amplifier is used before the antenna to amplify the signal. The modulated output signal is transmitted through a reconfigurable antenna and is observed by E4407B Spectrum analyzer. Observed spectrums for 2 different configurations are given in Fig. 9.

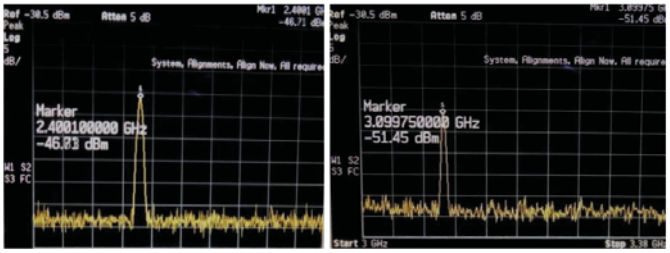

Fig 9. Output spectrum of received signal at 2.4GHz and 3.1GHz

VI. Reconfigurable Antenna

Reconfigurable antennas offer multiple functions by dynamically changing their properties. Reconfigurable antennas can be classified according to their reconfiguration techniques. It can be using lumped elements, variable capacitors, silicon photo switches, MEMS switches [13], or PIN diodes [14].The Planar Inverted-F antenna (PIFA) is resonant at a quarter- wavelength. It has good SAR properties. Since the radiation is away from the ground plane, the energy is directed away from the head. It also has a low profile and an omnidirectional pattern. The reconfigurability is achieved using the switching of PIN diodes. The simulations were done in AWR Microwave Office software. Geometrical dimensions of the antenna are specified in Fig. 10.

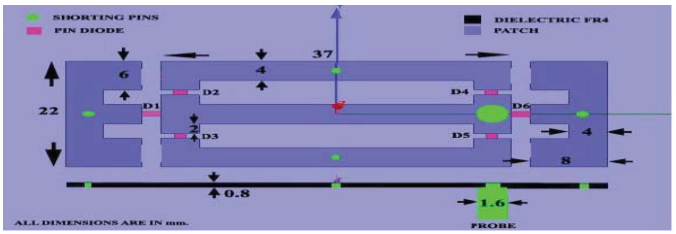

Fig 10. Reconfigurable PIFA dimensions

The S- parameter results for various modes are given below. Here 000110 correspond to PIN diode switches D1 D2 D3 D4 D5 D6. There are 6 PIN diode switches present. Hence 2^6=64 combinations of modes are possible. We have simulated some modes & stored these s- parameter results in a look up table.

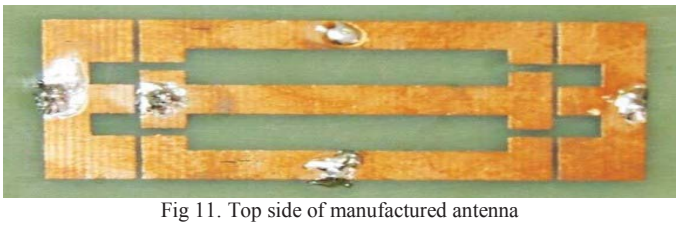

Fig 11. Top side of manufactured antenna

Table 2. Lookup table showing the major 14 modes

MODE	SWITCH CONFIG	FREQUENCY(GHz)
0	111111	1.5,4.4,4.7,5.7,6.62,7.29,7.94,8.2,9.75
1	011111	1.3,2,4.3,5.8,7.15,6.5,8.54
2	001111	2,5.78,8.4,8.76

8	000110	.77,1.82,5.79
9	100001	1.3,2.26,5.85

PIFA antenna was manufactured using FR4 as substrate of thickness 0.8mm with ε_r of 4.4. The top patch and ground plane was shorted using shorting pins to make it act as a PIFA antenna. Fig. 12 shows the measured S-parameter result using VNA.

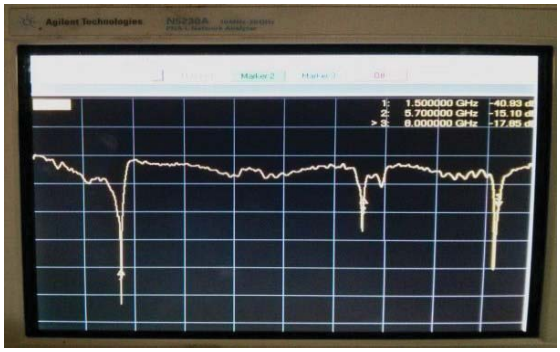

Fig 12. Measured S-parameter result for 000000 mode in N5230A VNA

VII. Conclusion

This paper has proposed a novel Cognitive Radio test bed system. A spanner shaped Ultra wideband patch antenna and frequency reconfigurable PIFA antenna has been proposed. A reconfigurable RF transceiver section has also been designed and setup. Spectrum sensing algorithm were tested using host computer in PXI module which verified the performance of sensing antenna over wide band frequencies. The UWB antenna shows a maximum power gain of [3.306dB] and has acceptable return loss for 2.23GHz-11.6GHz. The antenna is having omnidirectional radiation. Both the antennas were interfaced with a reconfigurable RF transceiver. Hence configurability has been achieved from baseband processor level to antenna level making all the components programmable. This system is not a complete design and needs future work to enhance the functionality and reliability

VIII. Futurescope

The current project has been worked on the physical layer. Suitable modifications can be made in MAC layer & Network layers to provide security, modulation data transfer & transfer of antenna mode data. Also processing time can be considerably reduced if FPGA modules are utilized for FFT computation. The performance of the reconfigurable antenna will depend on the mode chosen. Hence mode selection can be made more efficient by using fuzzy systems. Fine tuning of sub bands can be made possible using varactor diodes at suitable positions.

Abstract- **In today's world where science has made amazing advances so has the recent cars. These cars are more advanced than ever. They have more speed, state of the art engines and are very closely to these reasons there is a need to adapt a device which can continuously monitor all the various parameters of car. We propose a system which, in case of accident will records all the parameters and also help us to prevent any accident to happen. The Data Acquisition system (DAS) interface between the real world of physical parameters, which are analog , and the artificial world of digital computation and control ,CAN bus is a message-based protocol, designed specifically for automotive applications. CAN is a standard protocol for efficient and reliable communication between sensor, actuator ,controller and other nodes in real-time applications. This paper is aimed at the design of CAN protocol using PIC Microcontroller for vehicle monitoring and controlling system. The main feature is to monitor various parameters such a presence of CO level, temperature, fuel level and rain.. This paper describes the PIC based design of CAN Bus prototype for vehicle automation. Hardware interface circuit mainly consists of MCP2551 stand alone CAN-Controller with SPI interface. MCP2551 CAN Transceiver equipment ISO-11898 standard physical layer requirements. The design of software communication module includes system initialization and CAN controller initialization unit, message sending unit, message receiving unit and the interrupt service unit.**

Keywords-Vehicle Automation, Controller Area Network(CAN), LCD display, Dc Motor, Gas sensor, etc.

I. INTRODUCTION

The protocol was developed aiming at automotive applications. Today CAN have gained wide spread use and is used in industrial automation as well as in automotives and mobile machines. The CAN protocol is implemented in silicon. This makes it possible to combine the error handling and fault confinement facilities of CAN with a high transmission speed. The method used for distributing messages to the right receivers contributes to gaining a good use of the available bandwidth. This requires a simple transmission medium. A common transmission medium is a twisted pair of wires.. The development of CAN began when more and more electronic devices were implemented into modern motor vehicles. Examples of such devices include engine management systems, active suspension, ABS, gear control, lighting control, air conditioning, airbags and central locking. So, it is important that human drivers still have some control over the vehicle. Advanced in-vehicle information systems provide vehicles with different types and levels of intelligence to assist the driver. The introduction into the vehicle design has allowed an almost symbiotic relationship between the driver and vehicle by providing a sophisticated & intelligent driver-vehicle interface through an intelligent information network. This paper discusses the development of such a control framework for the vehicle which is called the digital-driving behaviour, which consists of a joint mechanism between the driver and vehicle for perception, decision making and control system.

All this means more safety and more comfort for the driver and of course a reduction of fuel consumption and exhaust emissions. The complexities of these control systems, and the need to exchange data between them meant that more and more hard-wired, dedicated signal lines had to be provided. Sensors had to be duplicated if measured parameters were needed by different controllers. Each device can decide if a message is relevant or if it should be filtered. This structure allows modifications to CAN networks with minimal impact. Additional non transmitting nodes can be added without modification to the network.

A microcontroller based data acquisition system that uses ADC to bring all control data from analogue to digital format is used. Since the vehicle information systems are spread out all over the body of a practical vehicle, communication module that supports to implement a one stop control of the vehicle through the master controller of the digital driving system. The proposed high-speed CAN bus system solves the problem of automotive system applications, also has a certain practical value and significance. Since the vehicle information systems are spread out all over the body of a practical vehicle, a communication module that supports to implement a one stop control of the vehicle through the master controller of the digital driving system. The proposed high-speed CAN bus system solves the problem of automotive system applications, also has a certain practical value and significance.

II. LITERATURE SURVEY

Vehicle control system implementation using CAN protocol discussed in [1] emphasizes the development and implementation of a digital driving system for a Semi-autonomous vehicle to improve the driver-vehicle interface. It uses an ARM based data acquisition system that uses ADC to bring all control data from analog to digital format and visualize that through LCD. The communication module used here is an embedded networking by CAN which has efficient data transfer. It also takes feedback of vehicle conditions like Vehicle speed, Engine temperature etc.,The development of such a control framework for the vehicle which is called the digital-driving behaviour, consists of a joint mechanism between the driver and vehicle for perception, decision making and control.

Traditional electronic control system can improve a vehicle dynamics, economy and comfort. But some problems also have come up, such as the body wiring complexity, space constraints and some reliability issues. In order to solve these problems, the vehicle network technology has been created. In-vehicle networking protocols must satisfy requirements which include, significant reduction of wiring harness, reducing body weight and costs, improving the efficiency of fault diagnosis, low latency times and configuration exibility and enhancing the level of intelligent control. Sub-systems (ECU) require the exchange of particular performance and position information within defined communication latency. Therefore the requirement for each ECU is to communicate via some kind of network technology such as CAN (Controller Area Network) bus.

Parameters	CAN	RS 232	SPI	I^2C
Async/Sync	Async	Async	sync	sync
Type	Multi-master	Peer to peer	Multi-master	Multi-master
Communication (Duplex)	Half	Full	Full	Half
Max. devices	112	2	Based on bus capacitance and bit rate	Based on bus capacitance and bit rate
Max speed	1Mbps	20Kbps	› 1Mbps	3.4Mbps

Table1. Comparison of CAN protocol with existing other protocol

By Using CAN protocol we can connect multiple microcontroller and other devices to a common CAN bus. To connect it to CAN bus we require a CAN transceiver in between bus and devices which enables the communication between all thing with great speed and priority. CAN based is a message based protocol which is designed specially for automotive vehicle.

III. METHODOLOGY

Considering all the approaches for controlling and monitoring system for vehicle, we come to conclusion that the CAN based systems avoid the number of wires and complexity in the system. In the various protocol system one drawback is that, the interference of noise may damage the data and will increase the complexity. So to implement controlling and monitoring system for vehicle we are using CAN protocol

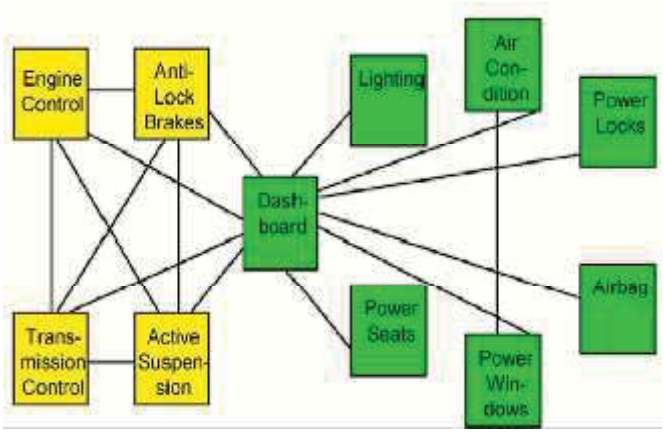

Fig 1 Existing system without CAN

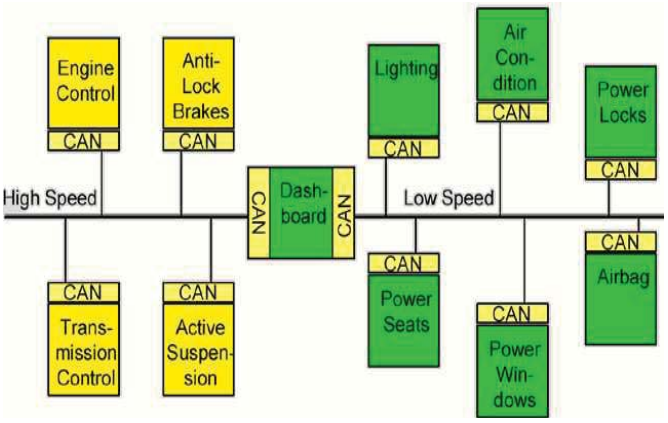

Fig 2 System using CAN

By using these methodology we are designing a system which we reduce no of wires and complexity of the system and the system is comfortable to the driver also and it will prevent many accident which got occur because of insufficient data available with the driver and it will overcome the disadvantages of analog system.

IV . ARCHITECTURE

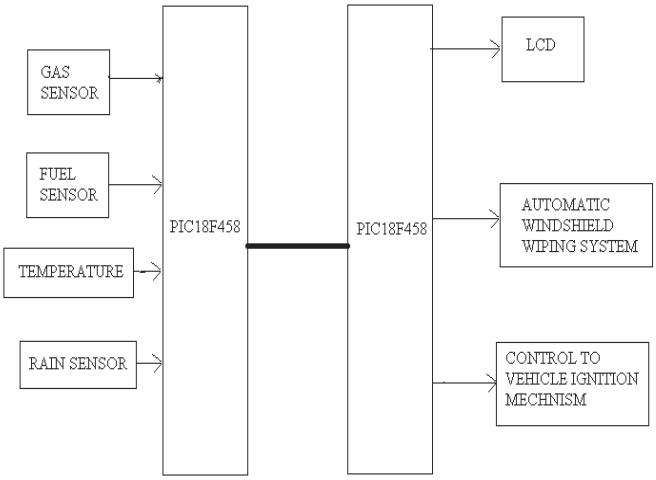

Fig 3 Proposed system architecture

A. *System architecture.*

The proposed system consists of Rain, fuel level, Gas and temperature sensor, CAN controller, motor driver circuit, PIC microcontroller, LCD.

B. *Operation*

The block diagram consists of various sensor which are continuously sensing various parameter and providing input to inbuilt ADC of PIC micro-controller. The ADC convert that analog data into the digital data and with the help of can controller sends that data to the receiving part which is another PIC microcontroller used for controlling the various parameter of vehicle. The 16*2 LCD is used to display data continuously and which is also used for indication. The motor is used to drive the windshield automatic when rain occurs. The buzzer is used for indicating when temperature crosses the threshold limit which is the maximum limit. The LED are used for indication of excessive presence of gas in vehicle.

C. *Microcontroller (PIC18F458)*

It is heart of our project. There are used various application such as automatically controlled products, remote controls, printer, scanner, office machines , appliances, toys and other embedded systems. PIC18FX58 devices have twice the Flash program memory and data RAM of PIC18F458 device (32 Kbytes and 1536 bytes vs.16 Kbytes and 768 bytes, respectively).The microcontroller circuit diagram is shown in less. The PIC18F458 devices include feature that allows the system clock source to be switched from the main oscillator to an alternate low-frequency clock source. Only PIC18F4X8 devices implement the Enhanced CCP module, analog comparators and the Parallel Slave Port. It is having a capacity of High current sink/source 25 mA/25 mA, Three external interrupt pins, Low-power, high-speed Enhanced Flash technology, Four Timer modules (Timer0 to Timer3),10-bit, up to 13-channel Analog-to-Digital Converter module (A/D) with Programmable Acquisition Time, Two External Clock modes, up to 48 MHz, Programmable Brown-out Reset (BOR) and Wide operating voltage range (2.0V to 5.5V)

D. *CAN transceiver (MCP2551)*

The MCP2551 is a high-speed CAN, fault-tolerant device that serves as the interface between a CAN protocol controller and the physical bus. The MCP2551 provides differential transmit and receive capability for the CAN protocol controller and is fully compatible with the ISO-11898 standard, including 24V requirements. It will operate at speeds of up to 1 Mb/s. Typically, each node in a CAN system must have a device to convert the digital signals generated by a CAN controller to signals suitable for transmission over the bus cabling (differential output).It also provide a buffer between the CAN controller and the high-voltage spikes that can be generated on the CAN bus by outside sources (EMI, ESD, electrical transients).

E. *Temperature Sensor*

LM-35 was Calibrated Directly in Celsius (Centigrade).It is Linear + 10 mV/C Scale Factor0.5C Ensured Accuracy (at +25C) .Rated for Full .55C to +150C Range. LM-35 is Suitable for Remote Applications. It is Low Cost Due to Wafer-Level Trimming. It Operates from 4 to 30 V and Less than 60-A Current Drain .It has Low Self- Heating 0.08C in Still Air. And Low Impedance Output, 0.1 for 1mA Load. It indicates the low level and high level temperature measurement and automotive ignition level gas exhausting, over heat when vehicle engine/motor speed was increased gradually.

F. *Rain Sensor*

The Raindrop Detection Sensor module is an easy-to-use and low cost drop recognition sensor. The sensor works through a series of exposed parallel traces on board which produces electrical variations when drops or water volume changes. By using microcontrollers or ADC ICs (Arduino and PIC) its fairly easy to convert the analog output from the sensor to digital values. This can be directly read by an Arduino or a comparator circuit if you wish to use it as a rain detection alarm. It can be used to monitor a variety of weather conditions.

G. *MQ-6 GAS Sensor*

MQ-6 gas sensor has high sensitity to Propane, Butane and LPG, also response to Natural gas. The sensor could be used to detect different combustible gas, especially Methane, it is with low cost and suitable for different application. Sensitive material of MQ-6 gas sensor is SnO2, which with lower conductivity in clean air. When the target combustible gas exist, The sensors conductivity is more higher along with the gas concentration rising. Please use simple electro circuit, Convert change of conductivity to correspond output signal of gas concentration.

H. *Power Supply*

The power supply most important for electronic circuits, which is provide the required power to microcontroller and other electronics

devices. which provide the required power to the PIC16F877A and other electronics devices. For this system we are using +5v power supply for buzzer and all different sensor which are used by us , .Also we required 3.3 v power supply for PIC microcontroller which is obtained by LM1117.For DC motor 12v supply is required which is taken from rectifiers output.

I. Buzzer

Lots of buzzers are available in the market depending upon the size and voltage range. We mostly use piezo buzzer working on 5v or 12v having a resonant frequency around 2000Hz. These buzzers are easily available in the local market and low costing. These buzzers require about 25mA-45mA current for proper sound generation if they do not get the desired current and voltage the output volume of the buzzer decreases or else we do not get any output at all. The controller cannot directly turn ON/OFF the buzzer as the output source as well as sink current of the current is below 20ma. So we have used an NPN transistor BC547 to ON/OFF the buzzer and provide the necessary current and voltage required for the buzzer.

V. CONCLUSIONS

This proposed system introduces an embedded system with a combination of CAN bus systems. Digital control of the vehicle is an important criterion of modern technology. With the rapid development of embedded technology, high performance embedded processor is penetrated into the automotive industry, which is low cost, high reliability and other features to meet the needs of the modern automobile industry. The proposed high-speed CAN bus system solves the problem of automotive system applications, also has a certain practical value and significance. With PIC as the main controller and it makes full use of the high-performance of PIC18f458, high-speed reduction of CAN bus communication control networks and instrument control. so as to achieve full sharing of data between nodes and enhance their collaborative work. This system features efficient data transfer among different nodes in the practical applications.

Abstract: Orthogonal Frequency Division Multiplexing (OFDM) is a bandwidth efficient modulation scheme and has become a popular technique for transmission of signals over wireless channels. It has been chosen for several current and future communication systems all over the world because of many features. However OFDM systems are extremely sensitive to time and frequency synchronization errors. Hence one of the most important tasks in OFDM receiver is time and frequency synchronization. Synchronization errors are errors are estimated and corrected before demodulation of subcarriers. We are proposing preamble based synchronization methods for error estimation. In this paper, only frequency synchronization process is considered. Simulation results are presented to confirm the performance of the proposed methods in two different channel conditions which are AWGN and multipath fading channel.

Keywords: OFDM synchronization, Carrier Frequency Offset, Frequency synchronization.

I. Introduction

The OFDM system transmits a large number of narrowband carriers, which are closely spaced. At the central frequency of the each sub channel there is no crosstalk from other sub channels. Thus there is no interference from other sub carriers at the peak of a desired sub carrier even though the sub carrier spectrums overlap [1]. So in order to assure a high spectral efficiency the subchannel waveforms must have overlapping transmit spectra and for this subchannels need to be orthogonal. This orthogonal modulation and demodulation can be achieved with the help of IFFT at transmitter and FFT at receiver. Recent advances in Very Large Scale Integration (VLSI) technology make high speed, large size Fast Fourier Transform (FFT) chips commercially affordable. Also substantial advancements in Digital Signal Processing technology made OFDM an important part of telecommunications landscape. In the 1990s, OFDM was exploited for mobile radio FM channels, High-bit rate Digital Subscriber Lines, Asymmetric Digital Subscriber Lines and Very-high-speed Digital Subscriber Lines. The first commercial use of OFDM technology was made in Digital Audio Broadcasting (DAB) which was started in 1995. OFDM is also used in Digital Video Broadcasting (DVB) and High Definition Television (HDTV). HiperLAN2 was defined in June 1999 which also uses OFDM. OFDM is being used in wireless LAN, and also for fixed broad-band access [2]. OFDM has successfully replaced Direct Sequence Spread Spectrum (DSSS) for 802.11a and 802.11g. Perhaps of even greater importance is the use of this technology in fourth Generation (4G) wireless systems.

II. OFDM Signal Description

In OFDM, multiplexed frequencies are orthogonal to each other and hence it is possible to arrange the carriers so that the sidebands of the individual carriers overlap and the signals can still be received without adjacent carrier interference. Cyclic prefix is a crucial feature of OFDM to combat the effect of multipath. Cyclic prefix is a guard interval placed at the beginning of an OFDM symbol, which is same as the last portion of the time domain OFDM symbol. Idea behind this is to convert the linear convolution (between signal and channel response) to a circular convolution. In this way, the FFT of circularly convolved signals is equivalent to

a multiplication in the frequency domain. Another advantage with the cyclic prefix is that it serves as a guard between consecutive OFDM symbols. Although the use of the CP prolongs the duration of OFDM symbols and results in a loss in data throughput, it has become a common practice in most commercial OFDM systems because of its advantages.

The baseband OFDM symbols consist of set of physical subcarriers whose frequencies are equal to the indices multiplied by the subcarrier spacing. N is the total number of subcarriers, usually a power of 2 to facilitate the FFT and IFFT operations [3].

In OFDM, data stream is mapped into number of complex symbols in frequency domain using either Quadrature Amplitude Modulation (QAM) or Quadrature Phase Shift Keying (QPSK). These complex symbols are modulated on N subcarriers by using N-point IFFT to get time domain complex OFDM symbol. The samples of baseband OFDM signal can be expressed as

$$x(n) = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} d_k(n)\, e^{\frac{j2\pi kn}{N}} \qquad n = 0,1,...N-1 \qquad \textbf{(1)}$$

Here $d_k(n)$ are the complex data symbols.

The total symbol duration is

$$\mathbf{T_{Total} = T_{CP} + T_{Sym}}$$

Where T_{CP} is CP duration and T_{sym} is effective symbol duration

III. Timing Error Estimation

Timing error or time offset θ occurs because of channel delay and multipath dispersion. Due to timing error the receiver's time-domain FFT window spans samples from two consecutive OFDM symbols. This results in inter-OFDM symbol interference leading to Bit Error Rate (BER) degradation [4].

Timing synchronization is performed to estimate timing error and it has two main objectives:

- Frame synchronization: The task of the frame synchronization is to identify the Preamble in order to detect a packet arrival
- Symbol-synchronization: The task of symbol timing is to identify the beginning of the symbol or symbol boundary

A. Proposed Algorithm for Timing Error Estimation

Realizable receiver structures usually follow the principle of synchronized detection i.e. synchronization parameters are first estimated and then used as if they are the true parameters. We developed method for timing error estimation which take advantage of the special structure in the training symbol and locate the start positions of OFDM bursts. The training symbol is used as preamble.

The preamble used for this algorithm has two identical halves of length N/2 and is the same used in S and C algorithm [5]. The proposed algorithm makes use of autocorrelation function (ACF) and cross correlation function (CCF) both.

We are simply multiplying both functions over certain window length. Metric of this proposed algorithm is given by

$$M(n) = P_{ACF} \times P_{CCF} \qquad \textbf{(2)}$$

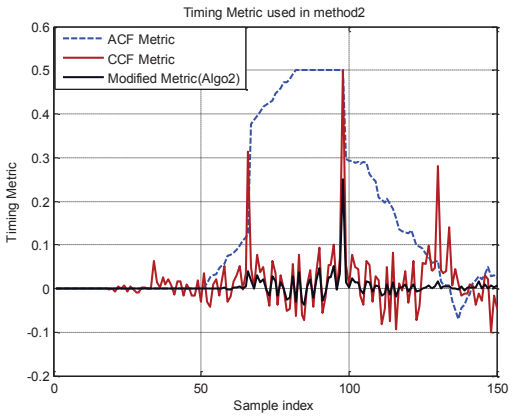

Figure 1 Timing metric of proposed algorithm without CP and with CP

Metric obtained using ACF, CCF and proposed algorithm are shown in Figure 1. Here CP is of length 16 samples. If maximum value of timing metric is higher than a predefined threshold, the peak is detected. If no peak is found, the frame is considered as empty and noise estimation is performed. From the sample right after the peak, first OFDM symbol starts.

IV. Frequency Error Estimation

In OFDM, frequency synchronization errors are actually Carrier Frequency Offsets (CFO). In a typical wireless communication system, the signal to be transmitted is up converted to a carrier frequency prior to transmission. The receiver is expected to tune to the same carrier frequency for down-converting the signal to baseband, prior to demodulation. However, due to device impairments the carrier frequency of the receiver need not be same as the carrier frequency of the

transmitter. When this happens, the received baseband signal, instead of being centered at DC (0MHz), will be centered at a frequency Δf which is equal to CFO. In general CFO is caused by unmatched local oscillators at the two ends of the communication links, Doppler shifts or phase noise introduced by nonlinear channel [6].
As the subcarriers are closely spaced in frequency compared to the channel bandwidth, the frequency offset must be kept within a small fraction of the subcarrier spacing to avoid severe bit error rate degradations.
So after timing synchronization next step is to estimate fractional carrier frequency offset (CFO) to align local oscillator frequency to the received carrier frequency.

A. Proposed Algorithms for Frequency Error Estimation

Method1

We are herewith proposing a scheme for fractional CFO estimation. Our proposed method utilizes the CCF generated for timing metric of method 2 required in timing synchronization. So no separate training symbol is required. This CCF function is shown in figure 2.
For CFO estimation, it is assumed that timing synchronization is done perfectly.
In this proposed method, we are using the fact that phase separation between two consecutive peaks of CCF function is proportional to CFO. Carrier frequency offset hence can be estimated using

$$\Delta f = \frac{\Delta\phi}{\pi T_u / 2} \quad \textbf{or} \quad \textbf{(3)}$$

$$\Delta f = -\frac{\angle y(k - N/2).y^*(k)}{\pi N/2} \quad \textbf{(4)}$$

Here $\Delta\phi$ is phase difference between two peaks of CCF function which are separated by time duration of Tu/2 or N/2. Any consecutive two peaks can be used.

Method 2

The training symbol used has two identical parts. The main difference between the two halves of this training symbol at receiver is a phase difference of

$$\varphi = \pi T \Delta f \quad \textbf{(5)}$$

The phase can be estimated by using

$$\hat{\varphi} = angle(\max(\mathrm{M(n)})) \quad \textbf{(6)}$$

Where M (n) is the timing metric of proposed algorithm2 and is shown in Figure1. Single peak is observed.

Fractional CFO is then estimated by

$$\Delta \hat{f} = \frac{\hat{\varphi}}{\pi T} \quad \textbf{(7)}$$

Method3

This method provides complete frequency synchronization and uses either method1 or method2 for estimation of fractional CFO. After timing synchronization and fractional CFO correction is done, integer frequency synchronization is performed. After N point FFT of OFDM symbols of the frame, integral shifts are carried out in all subcarriers and from this the shift for which the energy is maximum is found out. Argument of this maximum position is equal to integer frequency offset i.e.

Integer CFO = arg(max(energy)) (8)

B. Performance of Proposed method3

Fractional CFO is estimated and corrected using method1. This is coarse frequency synchronization. In the next step fine frequency synchronization is performed in which integer CFO is estimated and then corrected. For simulation in MATLAB, known value of CFO is inserted in the OFDM signal. This is done by multiplying the nth sample with

$$e^{\frac{j2\pi\varepsilon n}{N}}$$

Here ε is the normalized CFO. If the inserted CFO ε is 4.3, then the integer value of frequency offset inserted is 4 and fractional value of frequency offset inserted is 0.3. The amplitude of samples in preamble is kept such that the average power of preamble is almost equal to the OFDM symbols. There are in effect 214 non zero subcarriers having odd index with interleaved null subcarriers between successive non zero sub carriers. Major specifications used for simulation of this algorithm are depicted in Table 1.

Table 1 Simulation Parameters

FFT length N	512
Number of effective subcarriers	428
Constellation mapping	4QAM
Cyclic Prefix length	N/8=64
Number of simulation runs	100
SNR range	0 to 30 dB
Number of Symbols in frame	10

1) Performance of Proposed method3 for AWGN channel

Integer frequency offset is estimated using method3 after fractional CFO correction and performing FFT. Simulation is performed 100 times for SNR values of 30 dB and 5 dB. Histogram plots and scatterplot are generated for estimated integer CFO and scatterplot are obtained for estimated fractional CFO.

Figure 2 is a histogram plot of estimated integer CFO. This plot shows that for all 100 trials, estimated value of integer CFO is 4 which is equal to the actual inserted value. Scatterplot of estimated fractional CFO is depicted in Figure 3. This figure shows estimated values for 100 trials. All values are very close to actual inserted value which is 0.3. Total estimated CFO is calculated using

EstimatedCFO = integer_offset+fract_offset

Error is calculated for all trials using

CFOerr = ActualCFO-estimatedCFO

Mean of this error is calculated and found to be

Mean(CFOerr) = 2.4789e-005

In above discussion, value of SNR is 30dB.
Similar results are obtained for value of SNR=5dB
Mean of estimation error is found to be Mean(CFOerr) = 0.0015
It is clear that for low value of SNR, estimation error has been increased so the estimation accuracy depends on SNR value. Mean value of residual error is very less even for SNR= 5dB and is within tolerable level i.e. less than a percent of actual value.

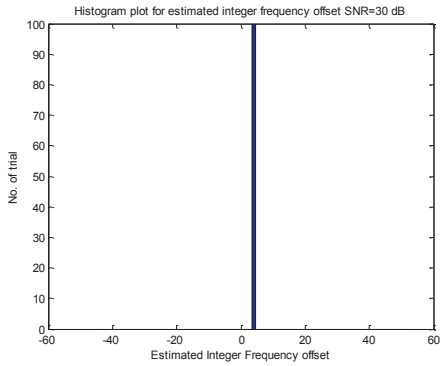

Figure 2 histogram plot of estimated integer CFO for SNR=30 dB (AWGN channel)

To demonstrate the performance of proposed methd3, reference design of Shimidl and Cox is considered. Figure 4 shows a plot of mean squared error vs SNR obtained using proposed method3 and reference method. Proposed method gives better performance than reference method. However improvement in performance is less. The mean squared error is calculated using equation (9).

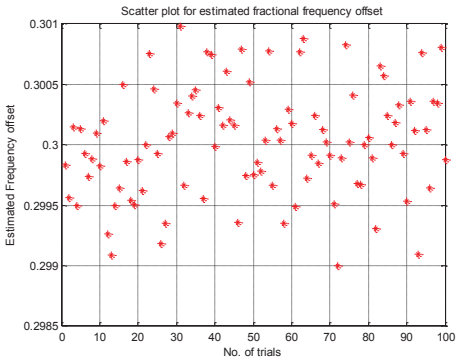

Figure 3 Scatterplot of estimated fractional CFO for SNR = 30 dB ((AWGN channel)

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(EstimatedCFO - ActualCFO)^2 \quad (9)$$

Here n = Number of trials

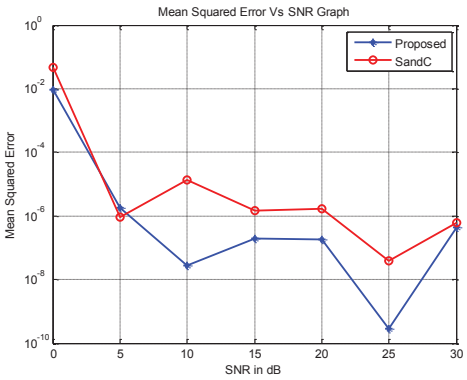

Figure 4 Mean squared error vs SNR, inserted CFO=4.3 (AWGN channel)

2) Performance of Proposed method3 for Multipath fading channel

Similar steps are performed for doing simulation of proposed method3 for multipath channel. As a multipath channel, Channel B of ITU Channel Model for Outdoor to Indoor and Pedestrian Test Environment is being considered. Initially the amplitude of samples in preamble is kept such that the average power of preamble is almost equal to that of the OFDM symbols. Inserted value of CFO is 4.3. Histogram plot is obtained and it is found that, for all 100 trials estimated value of

integer CFO is 4 which is equal to the actual inserted value for SNR=30 dB. Scatterplot of estimated fractional CFO is depicted in Figure 5. This figure shows estimated values for 100 trials. All values are very close to actual inserted value which is 0.3.

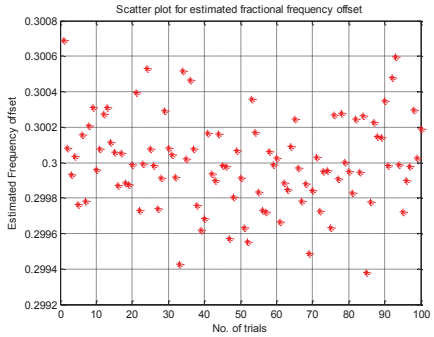

Figure 5 Scatterplot of estimated fractional CFO for SNR = 30 dB (Multipath fading channel)

Total estimated CFO is calculated and Mean of the error is found to be
Mean (CFOerr) = 1.4551e-006
Similar results are obtained for SNR=5dB
For 5dB SNR, in histogram plot it is found that, value is estimated correctly for 52 trials out of 100 trials. Mean error in CFO estimation for this case is found to be
Mean (CFOerr) = 0.3593

Residual error here is nearly 10% of the actual value which is not tolerable.
However it is found that estimation accuracy can be improved if the training symbol is boosted. After boosting of training symbol, the mean error was found to be
Mean (CFOerr) = 0.0303 for SNR =5dB

Now this residual error is less than 1% of the actual value and method gives good performance. Here value is estimated correctly for 95 trials out of 100 trials.

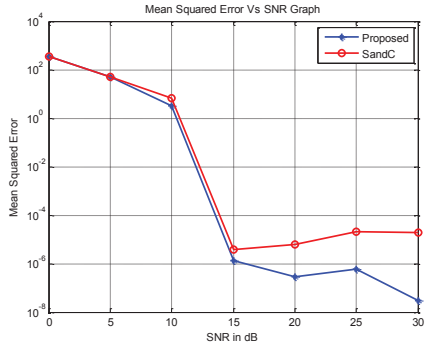

Figure 6 Mean squared error vs SNR, inserted CFO=4.3 (Multipath fading channel)

100 simulation runs are performed to evaluate the mean squared error (MSE) of CFO estimation versus SNR. In each run, the timing offset and the channel are constant. Figure 6 shows a plot of mean squared error vs SNR obtained using proposed method3 and reference method for multipath fading channel. For both Proposed method and reference method, average power in training symbol is 3dB more than the OFDM symbol. The two methods have similar performance for SNR up to 10 dB however MSE performance of Proposed method 3 is better than the reference method for SNR more than 10 dB.

V. Conclusion

Method3 of frequency error estimation is analyzed in detail. Estimation error (residual error) values for two channel conditions are summarized in Table 2. From this result, we conclude that our proposed method3 shows satisfactory performance. From MSE graph, it is clear that our proposed method3 shows performance nearly same to that of standard reference method. Performance is tested for multipath channel environment also.

Table 2 Estimation error values

AWGN Channel, SNR=30 dB	2.4789×10^{-5}
AWGN Channel, SNR=5 dB	1.5×10^{-3}
Multipath Fading Channel, SNR=30 dB	1.4551×10^{-6}
Multipath Fading Channel, SNR=5 dB	3.593×10^{-1}
Multipath Fading Channel, SNR=5 dB (Boosted training symbol)	3.03×10^{-2}

***Abstract*—This paper presents the main use of drum handling and tilting equipment in the industries. This device is developed to reduce the human efforts and to safeguard the operator from hazardous chemicals. This results in efficient and safe operation. Also to study the effects of this device after implementation in industry.Also study the effect of material handling and tilting on the human.**

Keywords—Worm & Worm gear, sprocket with pulley, chain, Drum, paper roll, clamping device & supporting frame.

I. INTRODUCTION

In many industries the drum is handled manually. In workplace, the drum needs to be loaded, unloaded ,transported, tilted etc, manually. Manual drum handling and tilting takes much time, and requires more number of workers. It is also risky and hazardous to the operator. In chemical industries number of different chemicals are stored in drums. It is requires to handle carefully the process of loading, unloading, and tilting. Company cannot use pump to drain out the chemicals (is in liquid form) from the drum or barrels because of its cost. Company requires effective handling and tilting equipment for effective performing the given operation. This paper successfully provides an successful and a safe solution to all the industries who deal in the drum handling as a part of their daily routine.

II. EASE OF USE

When chain is pulled, the pulley rotates in anticlockwise direction hence it rotate the worm shaft in anticlockwise direction, the power is transmitted to fixed end of holding device in clockwise direction (Both worm gear and adjustable holding frame) and it tilts the drum up to 90°.

When the chain is released the pulley rotates in clockwise direction due to which the worm gear rotates in clockwise direction and both worm wheel and adjustable holding frame rotates in anticlockwise

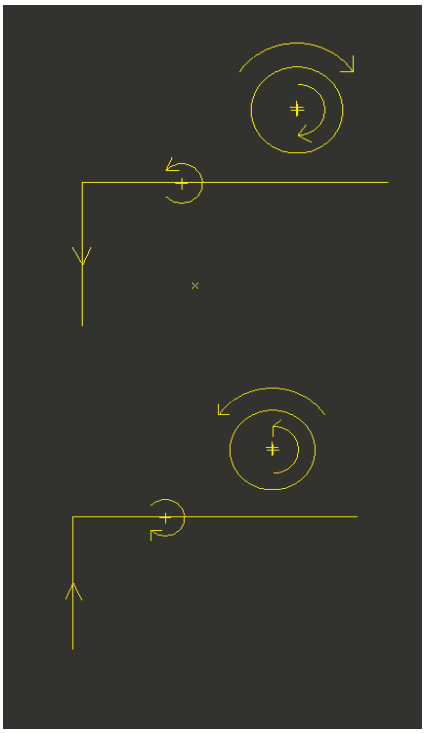

Fig.1- General operation

direction. After that the drum comes back to its original position (vertically stands).

III. CONSTRUCTION

It consist of supporting frame, holding frame, four bearings, worm and worm gear, pulley, chain etc. A holding frame is placed over the supporting frame which is to be used to hold the drum. This holding frame is adjustable and can hold drums of diameter ranging between 60 cm to 65 cm. There are four bearings used in the device two are taper roller bearings and two are ball bearing. These two taper roller bearing are attached to the both end of adjustable holding frame. Non intersecting non parallel worm and worm gears are used. Two ball bearings are attached to both ends of the worm shaft. The last part comprises of pulley which is connected to the end of the extended worm shaft. The sprocket is provided over the pulley and the chain is placed over it to pull the pulley.

A. Units

Abbreviation	Full form
Cm	Centimeter
Kg	Kilogram
N	Newton

IV. WORKING

As specified in the construction supporting frame, holding frame, four bearings, worm and worm gear ,pulley, chain etc are the working component. The working start with the Drum or paper roll which is fixed between the adjustable holding frame ranging from 60 to 65 cm in diameter and the frame can sustain 300 kg load. The frame is connected to the taper roller bearings. Taper roller bearings are used because this type of bearings can sustain more radial load. One side of the holding frame (first taper roller bearing) is fixed, another side of holding frame goes through taper roller bearing and connected to the worm gear. For this device we use worm and worm gear because this gear are self locking.

When the chain is pulled, the pulley rotates. Hence the worm shaft rotate due to Non intersecting non parallel gear the worm gear rotate and the drum is tilted up to 90°. Once the material or chemical is removed from the drum the chain is released & drum comes to its original position. The drum does not come back to its original position automatically because the gears are self locking.

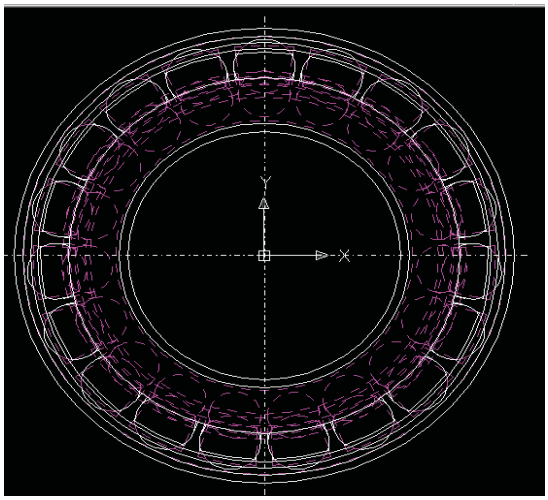

Fig.2-CAD of taper roller bearing.

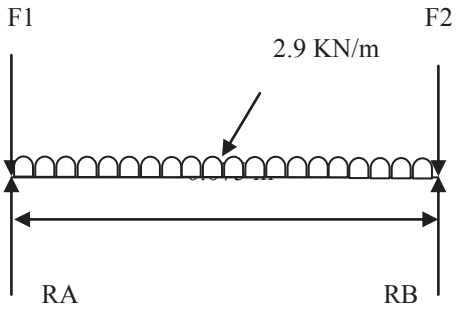
Bearing selection is done according to the static and dynamic loads on the bearing. By considering the overall weight of the system of nearly 300kgs and considering 25% excess weight according to safety assumptions the bearing selected is 32006 X/Q from SKF online catalogue.

V. CALCULATIONS



GIVEN – LOAD=300 KG A=5 CM

=300*9.81 b=65 cm

=2943 N c=5 cm

To calculate the force

F1=[w1(b+c)+w2c]/(a+b+c)]

=[2943(65+5)+(2943*5)]/(5+65+5)]

=2943 N

F2=[w1a+w2(a+b)]/(a+b+c)]

= 2943 N

F=F1+F2

=5886N =5.885 KN

Shear Force Calculations

RA-F1-(UDL*L)-F2+RB=0

RA-2.943-0.02175-2.943+RB=0

RA+RB=6.10 KN

Bending Moment Calculation

-RA*0+2.9*0.075*(0.075/2)

+F2*0.075-RB*0.075=0

$8.156*10^{-3}+0.2207=0.075*RB$

RB=3.05 KN

RA+RB=6.10 KN

RA=3.10 KN

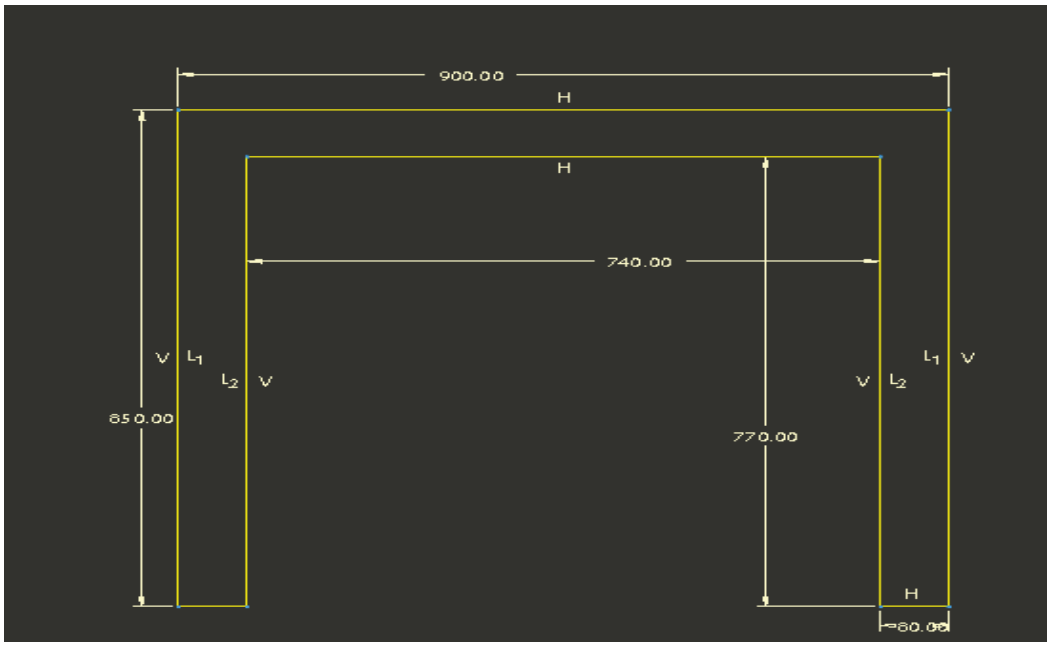


Fig. 03- CAD drawing of supporting base

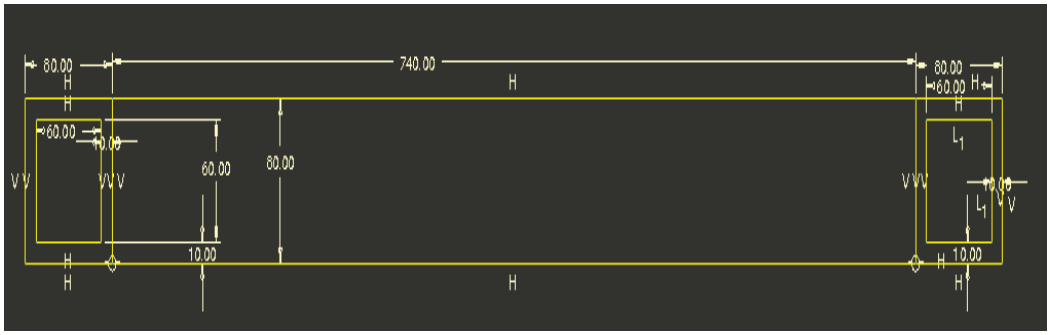

Fig. 04- CAD drawing for Calculating volume.

Shear stress Calculation

A1=A3=0.068 m^2

A2=0.0592 m^2

Total area=A1+A2+A3

=0.1952 m^2

$$\sigma = \frac{F}{A} = \frac{5.886}{0.1952} = 30.15\frac{kN}{m^2} = 0.03015\frac{N}{mm^2}$$

According to standard value- E= 211 GPa
= 211x10^3 MPa.

$$E = \frac{\sigma}{\varepsilon}$$

$$\varepsilon = \frac{0.03015}{211 * 10^3} = 1.4289 * 10^{-7}$$

$$\varepsilon = \frac{\delta V}{V} = \frac{\delta V}{6.832 * 10^{-3}}$$

$$\delta V = 9.7622 * 10^{-10}\ m^3$$

VI. CONCLUSION

From this paper we have successfully designed a Drum Handling Equipment for reducing the accidents in the industries. After implementing this mechanism in industries we claim to reduce the accident and to provide safety to the worker from hazardous chemicals. Results of this mechanism in terms of mechanical calculations are- sustainable load 300kg load, total force= 5.886 KN, Stress=0.0315 N/mm^2, Volume=$6.832*10^{-3}$ m^3, Strain =$9.7622*10^{-10}$ m^3.

Abstract—**Many countries in the world are using nuclear energy to fulfill their energy requirement due to increasing demand of electricity. But the fuel used in NPP is highly radioactive & ionizing radiations emitted by these fuels is harmful for all living beings in the environment. If the exposure of these ionizing radiations is more than optimum value then it cause various health issues. Probability of ionizing radiation exposure is very high at time of Decommissioning process of NPP after completing its lifespan. Decommissioning is nothing but he administrative and technical actions taken to allow the removal of regulatory controls from a nuclear facility and typically includes dismantling the facility.**

Measure of energy deposited by radiation in a target is known as dose of radioactive element & pathway of a contaminant (Dose of radioactive element) may take to reach humans or other living organisms is called as exposure pathway like ingestion, inhalation, skin contact, etc. This paper contains detailed information of decommissioning of NPP, Ionizing Radiations Exposure due to NPP, Dose Limits of Ionizing Radiations for NPP Staff, Design Aspects for Radiation Protection in NNP & Steps for ALARA and Results of a Test Case For Decommissioning Dose Rates Calculations

Keywords—***Decommissioning; Dose Rate; Ionizing Radiations; exposure route; radioactive element***

I. INTRODUCTION

Radioactive material is handled by almost every country in the world may, for example, be in the form of a source used for medical purposesorfuel in a nuclear power plant. The facilities that use and handle radioactive material vary in size from large, complex sites, such as nuclear fuel cycle facilities andnuclear power plants, to smaller facilities such as manufacturing plants research and university laboratories. Now questions will arise regarding the effects of dose of ionizing radiation's exposure and ageing or usefulness of these facilities. Then they will require the implementation of a decommissioning strategy. Thousands of facilities in the worldhave been estimated that they will require some degree of decommissioning & currently some are undergoing decommissioning.

Both man-made and natural sources of ionizing radiation contribute to human exposure. The exposure of workers and public, to low levels of radiation from NPP have become an integral part of industrialized society. This paper consists of Planning, Strategy , Policy & techniques of decommissioning as well as dose rate calculations for NPP staff.

II. DECOMMISSIONING OF NPP

Decommissioning is an invasive process that presents industrial and chemical hazards as well as radiological ones, and indeed the non-radiological hazards generally represent greater overall risk to workers (IAEA, 2013; Jeong and Lim, 2009).

Decommissioning include both technical & administrative actions ones that must be accomplished to show that the facility can be released for unrestricted use or otherwise reused. The safety and economic considerations defined operating lifetime of nuclear facilities. NPPs are designed for an operating lifetime of several decades & it can be extended to up to 60 or more years by appropriate replacement, refurbishment or upgrading of some equipment called as “life extension”. The closure of operating life of nuclear installation & the decommissioning sequences should be planned at the design stage and may be related to termination of the design life of major components;

-Excessive operating costs compared with competing energy sources

-The conclusion of a research program that has achieved its goal and Safety issues

- Changes in government policy and accident or unplanned event requiring the final decommissioning to be performed.

A. Decommissioning Policy

It refers and includes government policy, all governmental choices, as described in laws, standards,mandatory requirements andregulations that will influence the framework in which decommissioning takes place.

B. Decommissioning Strategy

It includes all aspects of decommissioning and industrial approaches which may affect costsandprojects that are proposed to national competent authorities in the context of application for permission to decommission.

C. *Decommissioning Planning*

Careful and organized planning and clear identification of the objectives of the decommissioning is essential to ensure successful decommissioning. Before the start of decommissioning activities the regulatory body provides guidance in this respect, and reviews and approves the decommissioning plan.

Three stages of planning are as follows:

- Initial planning
- Ongoing planning
- Final planning

III. DECONTAMINATION TECHNIQUES

The removal of contamination from surfaces of facilities or equipment by heating,washing ,electrochemical orchemical action, mechanical cleaning or other techniquesis known asdecontamination.

Objectives of decontamination are as follows :

- To decrease radiation exposure;
- To salvage materials andequipment;
- To reduce the magnitude of the residual radioactive source and volume of materials requiring storage and;
- To restore site and facility, or parts thereof, to an unconditional-use situation;
- To remove loose radioactive contaminants and fix the remaining contamination in place in preparation for protective storage or permanent disposal work activities;
- To reduce the protective storage period or to minimize long-term surveillance requirements.

Some form of decontamination is required in any decommissioning program. As a minimum, the floor, walls, and external structural surfaces within work areas should be cleaned of loose contamination, and simple water rinsing of contaminated systems is performed.A decontamination program may also require a facility capable of treating secondary waste from decontamination.

The proven and emerging decontamination techniques which may be used to accomplish the goals of decommissioning activities have been discussed by the Technical Advisory Group of the Organization for Economic Cooperation and Development-Nuclear Energy Agency (OECD-NEA), a Cooperative Program on Decommissioning. International organizations which dealing with decommissioning in various roles and aiming at different goals are:-

1. UNO-IAEA (United Nations Organization-International Atomic Energy Agency)

2. OECD-NEA (Organization for Economic Cooperation & Development)

3. EC (European Commission)

4. WANO (World Association of Nuclear Operators)

5. WENRA (West European Nuclear Regulator Association)

A. *What do expert agencies say*

Several national and internationalagencies study different substances in the environment to determine if they can cause cancer. American Cancer Society looks towards these organizations to evaluate the risks based on evidence from research studies.

The International Agency for Research on Cancer (IARC) is part of the World Health Organization and plays major role in identifying the causes of cancer as well as human carcinogens.

The US Environmental Protection Agency (EPA) sets limits for exposure to x-rays and gamma rays in part because it recognizes that this form of radiation can cause cancer. For more information on the classification systems used by these agencies, see Known and Probable Human Carcinogens.

B. *Safetyconsideration during decommissioning of nuclearfacilities :*

Workers, the public and environmentshould be properly protectedat all phases of decommissioning from hazards resulting fromthe decommissioning process. During decommissioning a thorough safety assessment of thehazards involved should be conducted todefine protective measures, as part of a defense in depth system. Such measures may be different from those in place duringthe operation of the installation (IAEA, 1999).

The early stage of decommissioning of nuclear installations often involves theremovalof significant quantities of radioactivematerial, including fuel and operational waste. After this,the total contamination and activation of the installation is significantand has to be taken into account in the safety assessment(IAEA, 1999).

There is great importance for implementation of particular activities such as decontamination,cutting and handling of large equipment, and the progressivedismantling or removal of some existing safety systems. These activities have the potential for creatingnew hazards. An important objective during decommissioning is,therefore, that the safety aspects of these decommissioningactivities, such as the removal of existing safety system, beadequately assessed and managed, so as to mitigate any potentialexposure. Integrity of spent fuel, when still stored on-site in a fuelpool, should be considered and maintained. Fire protection andsuppression for the complete site should be included in thedecommissioning plan (IAEA, 1999).

IV. A TEST CASE FOR DECOMMISSIONING DOSE RATES CALCULATIONS OF NUCLEAR POWER PLANT STAFF :

Estimate the total Estimated Dose for exposure to ionizing radiation from external and internal sources on a young 19

years old male who is working in a Nuclear Power Plant which is in process of Decommissioning.

The worker is exposed to I-129 in the air at the workplace with activity concentration of 0.6 Bq/m3 and Am-241 (americium-241) in the water. The total daily ingestion rate of water is assumed to be 3 L/day with only 1/3th being consumed at the workplace. The activity concentration of Am-241 in the water is estimated at 0.008 Bq/L.

The worker is exposed also to accident ingestion of Pu-239 in the soil with ingestion rate of 20 mg over 24 hours. The Pu-239 activity concentration in the soil at the workplace was measured to 7 Bq/kg.

This young male has one meal eaten from food prepared at the workplace so that 1/3th of the average amount of food (presented in TABLE 3) is consumed in the workplace. The radionuclide activity concentration is measured in three food groups which are part from adult's meal. First food group is meat with activity concentration 1.1x10-5Bq/g from Cs-137. The second food group is dairy products with activity39 x 10-4Bq/g from Cs-137 again and the third group in the meal is vegetables with activity concentration 11 x 10-3Bq/g from Ra-226.

The radiation exposure (external) from artificial sources has been measured by instruments and estimated to be 1.4 x 10-2 mSv above the natural background radiation.Assume a 52-week work year and a 4-day work week with 10 hours work day.

GIVEN DATA:

- Age of young male = 19 years
- No. of working weeks in 1 working year = 52
- No. of working days in 1 working week = 4
- No. of working hrs. in 1 working day = 10
- Radiation Exposure (external) from Artificial Sources = ED(external)= 1.4 x 0.01 mSv
- CF = Conversion Factor: The factor of 365 days is required to convert the inhalation or ingestion rate from units/day to units/year
- EF = Exposure Factor =

$$\frac{(\text{working weeks per year}) \times (\text{working days per week})}{365 \text{ days per year}} \quad \text{.....(1)}$$

$$= \frac{52 \times 4}{365} = 0.5699$$

- Air inhalation Radiation Exposure Data:
  - Contaminat = I-129
  - Activity Concentration of I-129 = 0.6 Bq/m^3
  - Standard Value for Daily Intake of Air = 21 m^3/day
- Hence value for daily intake of air in working hrs. = Inhalation Rate (IR) =

$$\frac{\text{Standred Value for Daily Intake of Air} \times \text{No of working hrs. in 1 working day}}{\text{No of total hrs in 1 Day}} \quad \text{.....(2)}$$

= 8.75 m^3//Day

- DCF of Radionuclide I-129 for air Inhalation = 6.7×10^{-8} Sv/Bq

- Water ingestion Radiation Exposure Data:

- Contaminant = Am-241
- Activity Concentration of Am-241= 8×10^{-3} Bq/L
- Standard Value for Daily Intake of Water = 3 L/day
- Hence value for daily intake of water in working hrs. = Ingestion Rate (IR) = $1/3$ rd of Standard Value for Daily Intake of Water = 1 L/Day
- DCF of Radionuclide Am-241 for water Ingestion = 5.7×10^{-7} Sv/Bq

- Soil ingestion Radiation Exposure Data:

- Contaminant = Pu-239
- Activity Concentration of Pu-239= 7 Bq/Kg
- Standard Value for Daily Ingestion rate of Soil = 20 mg/day = 20 mg/24hrs.
- Hence value for daily Ingestion rate of Soil in working hrs.=Ingestion Rate (IR) =

$$\frac{\text{Standred Value for Daily Ingestion of soil} \times \text{No of working hrs. in 1 day}}{\text{No of total hrs in 1 Day}} \quad \text{.....(3)}$$

$$= \frac{20 \times 10}{24} = 8.33 \text{ mg/Day}$$

- DCF of Radionuclide Pu-239 for Soil Inhalation = 5.6×10^{-7} Sv/Bq

- Food ingestion Radiation Exposure Data:

<u>Food Group 1 (Meat)</u>

- Contaminant = Cs-137

- Activity Concentration of Cs-137= 1.1×10^{-5} Bq/gm
- Standard Value for Daily Ingestion of Food Group 1 = 169 gm/person/day
- Hence value for daily Ingestion of Food Group 1 in working hrs. = Ingestion Rate (IR) = $1/3$ rd of Standard Value for Daily Ingestion of Food Group 1 = 56.33 gm/person/Day
- DCF of Radionuclide Cs-137 for Food Group 1 Ingestion = 1.3×10^{-8} Sv/Bq

Food Group 2 (Dairy Products)

- Contaminant = Cs-137
- Activity Concentration of Cs-137= 39×10^{-4} Bq/gm
- Standard Value for Daily Ingestion of Food Group 2 =573 gm/person/day
- Hence value for daily Ingestion of Food Group 2 in working hrs. = Ingestion Rate (IR) = $1/3$ rd of Standard Value for Daily Ingestion of Food Group 2 = 191 gm/person/Day
- DCF of Radionuclide Cs-137 for Food Group 2 Ingestion = 1.3×10^{-8} Sv/Bq

Food Group 3 (Vegetables)

- Contaminant = Ra-226
- Activity Concentration of Ra-226 = 11×10^{-3} Bq/gm
- Standard Value for Daily Ingestion of Food Group 3 = 250 gm/person/day
- Hence value for daily Ingestion of Food Group 3 in working hrs. = Ingestion Rate (IR) = $1/3$ rd of Standard Value for Daily Ingestion of Food Group 3 = 83.33 gm/person/Day
- DCF of Radionuclide Ra-226 for Food Group 3 Ingestion = 2.2×10^{-7} Sv/Bq

SOLUTION :

Estimating Air Inhalation Radiation Exposure :

The committed dose from internal radiation exposure as a result of air inhalation can be estimated with the equation

$$\boldsymbol{ED_a} = \mathbf{C} \times \boldsymbol{IR} \times \boldsymbol{CF} \times \boldsymbol{EF} \times \boldsymbol{DCF} \quad \textbf{.....(4)}$$

= 0.073169 mSv

The estimated 50-years committed dose from I-129 , as a one year of inhalation at the workplace , is 0.073169 mSv.

Estimating Water Ingestion Radiation Exposure :

The committed dose from internal radiation exposure as a result of water ingestion can be estimated with the equation $\boldsymbol{ED_w} = \mathbf{C} \times \boldsymbol{IR} \times \boldsymbol{CF} \times \boldsymbol{EF} \times \boldsymbol{DCF}$ .....(5)

= 0.094854mSv

The estimated 50-years committed dose from Am-241 , as a one year of ingestion at the workplace , is 0.094854 mSv.

Estimating Soil Ingestion Radiation Exposure :

The committed dose from internal radiation exposure as a result of soil ingestion can be estimated with the equation :

$$ED_S = \mathbf{C} \times \boldsymbol{IR} \times \boldsymbol{CF} \times \boldsymbol{EF} \times \boldsymbol{DCF} \quad \textbf{.....(6)}$$

=0.0067951mSv

The estimated 50-years committed dose from Pu-239 , as a one year of ingestion at the workplace , is 0.0067951mSv.

Estimating Food Inestion Radiation Exposure :

The committed dose from internal radiation exposure as a result of food ingestion can be estimated with the equation := 0.043964 mSv

The estimated 50-years committed dose from Cs-137, Ra-226 , as a one year of ingestion at the workplace , is 0.043964 mSv.

Total Estimated Dose for Ionizing Radiation :

ED = 0.13888 mSv

The estimated dose from both internal & external radiation exposure to ionizing radiation at the workplace , is 0.13888 mSv.

V. Design Aspects for Radiation Protection in Nuclear Power Plant :

- Plant layout, Proper design and adequate shielding:

  Prescribedesign values for the radiation level at a specified distance from the equipment and for the general radiation fields in different areas of the plant. The plant layout is such that the areas are segregated according to their radiation levels and contamination potential. The design, layout of areas and equipment, maintenance approach and shielding, etc. are made such that the collective dose to the station personnel would be “as low as reasonably achievable” (ALARA).

- Limits of air contamination levels in different zones of the plant:

  Made provision of ventilation such that in full-time occupancy areas of the plant and the airborne contamination are maintained below 1/10 Derived Air Concentration.

- Proper selection of materials/componentsto control source:

  Select Materials which are used in plant systems in such a way that the activation products arising from the base material or the impurity content do not significantly contribute to radiation exposures.

- Design limit for collective dose:

Specify a limit on the collective dose at the design stage of each NPP that adequate provisions for radiation protection are made in the design of plant to keep radiation levels in different areas below design levels.

VI. Dose Limits of Ionizing Radiation for NPP Staff

Following are the dose limits for exposures to ionizing radiations for occupational workersprescribed by AERB :

A. Effective dose (whole body)

- 20 mSv/year averaged over 5 consecutive years, calculated on a sliding scale of 5 years. (The cumulative effective dose in the same 5-year period shall not exceed 100 mSv.)
- A maximum of 30 mSv in any year.

B. Equivalent dose (individual organs)

- Eye lens 150 mSv/year.
- Skin 500 mSv/year.
- Extremities 500 mSv/year (hands and feet).

C. Pregnant woman

- Equivalent dose limit to the surface of the woman's lower abdomen (for the remaining period of pregnancy) – 2 mSv.
- Annual Limit on Intake (ALI) for radionuclide's – 0.05 ALI. (For the remaining period of pregnancy.)

D. Apprentices and students (above the age of 16 years)

- Effective dose (whole body): 6 mSv/year.
- Equivalent dose (individual organs)

  - Eye lens 15 mSv/year.
  - Skin 50 mSv/year.
  - Extremities 50 mSv/year (hands and feet).

VII. Steps for ALARA("as low as reasonably achievable") exposures:

Working procedures and methods are examined in order to meet the objectives of the ALARA and to reduce the possibility of doses resulting from radiation jobs. The exposures are kept ALARA by implementing the following operational aspectsduring the operational stage of the NPP:

- Implementation of contamination control procedures andradiation protection.
- Use of proper protective equipment.
- Adherence to approved operating and maintenance procedures.
- Implementation of radiation protection training and qualification programs and conduct of refresher courses to impart ALARA concept and awareness.
- Proper work planning and its practical implementation through the issuance of Radiation Work Permit and dose budgeting for each operation.
- Constitution of an ALARA committee at the plant level.
- Planning and preparedness for unusual events.

VIII. Results and discussion

By studying Decommissioning of NPP & Dose Rate Calculations for NPP Staff I can able to :-

- Understand the Scope of Decommissioning as well as Decontamination Techniques & Spent-Fuel Management
- Know the dangers of Ionizing Radiations Exposure due to NPP & Dose Limits of Ionizing Radiations for NPP Staff
- Get familiar with Design Aspects for Radiation Protection in NNP & Steps for ALARA
- Calculate the Results of a Test Case For Decommissioning Dose Rates Calculations for NPP Staff
- Get the information about Safety, Health & Environment Protection as well as International Organizations for Nuclear energy.

***Abstract*-With the development of industry manufacturing technology, fine surface finish is in high demand in a wide spectrum of industrial applications. Magnetic abrasive finishing (MAF) is one of the advanced finishing processes capable of producing excellent surface finish of the order of few nanometers. MAF process is used for fine finishing of flat surfaces as well as internal and external surfaces of tube type work pieces. The process can finish ferromagnetic as well as non-ferromagnetic materials. The MAF process is becoming popular due to its ability to give repeatable and consistent results. However, as the surface finish requirement increases, the operational cost of this process increases exponentially. Quality, cost, time and efficiency of this process can be improved significantly by choosing the optimum values of process parameters. This paper therefore presents a well-known statistical method known as Principal Component Analysis (PCA) to find the optimal combination of process parameters of MAF process for multi-objective optimization considering average normal force and average finishing torque as objectives. The results of the PCA are compared with the previously published results.**

Keywords-Magnetic abrasive finishing; multi-objective optimization; principal component analysis.

I. INTRODUCTION

Robust design is an engineering method of quality improvement that seeks to obtain a lowest cost solution to the product design specification based on the customer's requirements. The Taguchi method, which combines the experimental design techniques with quality loss considerations, is the conventional approach to achieve robustness. This method can only be used in a single-response case; it cannot be used to optimize a multi-response problem. However, a customer normally considers more than one quality characteristic in most manufactured products and the quality characteristics are usually correlated. Engineering judgment has up until now been used primarily to optimize the multi-response problem in the Taguchi method (Phadke, 1989). Unfortunately, an engineer's judgement increases the uncertainty during the decision-making process. Another approach to solve this problem entails assigning a weight for each response (Hung, 1990; Shiau, 1990; Tai *et al.*, 1992). Nevertheless, determining a definite weight for each response in an actual case still remains difficult. Another method employs the regression technique (Logothetis & Haigh, 1988; Pignatiello, 1993). However, such an approach increases the computational process complexity, and the possible correlations among the responses may still not be considered. In addition, a factor which is significant in a single-response case may not be significant when considered in a multi-response case. Therefore, a more effective approach is required to solve this complicated problem [1].

In this work, a systematic procedure via principal component analysis (PCA) is proposed for multi-objective optimization considering average normal force and average finishing torque as objectives. By using PCA, a set of original responses is transformed into a set of uncorrelated components so that the optimal factor/level combination can be found.

II. LITERATURE REVIEW

Taguchi method have been applied by many researchers for multi-objective optimization of MAF process. Yang et al. [2] performed the operations using Taguchi experimental design, considering the effects of magnetic field, pole rotational speed, feed rate, working gap, abrasive, and lubrication. The optimal parameter conditions was obtained after experimental data analysis, the quality surface roughness (R_{max} = 0.1 μm) which is similar to a mirror surface was obtained after confirmatory tests. The different optimal parameter conditions were obtained for surface roughness and material removal weight. Singh and Shan [3] studied the effect of key parameters i. e. magnetic flux density, volume flow rate and number of cycles on the material removal and percentage improvement in surface roughness using response surface methodology. Singh et al. [4] applied the Taguchi design of experiments to find out important parameters influencing the surface quality generated. Important parameters influencing the surface quality generated during the MAF are identified as: (i) voltage (DC) applied to the electromagnet, (ii) working gap, (iii) rotational speed of the magnet, and (iv) abrasive size (mesh

number). They determined the effect of process variables on the surface finish and both the forces (normal magnetic force and cutting force). Kala and Pandey [5] measured the finishing force and torque for a double disk magnetic abrasive finishing process. Investigations were made to understand the effect of process factors namely upper and lower working gap rotational speed, abrasive weight percentage on the normal finishing force and finishing torque using Taguchi L_9 orthogonal array.

However, the Taguchi approach in real sense is not optimization technique. Moreover, it can be applied only to single objective problem and in case of conflicting multi-objective optimization problem it gives different levels, thus it becomes difficult to interpret this result to achieve the best performance. Hence, this paper discusses the application of PCA to multi-response problem with a case study.

III. PRINCIPAL COMPONENT ANALYSIS

In PCA, a set of original responses is transformed into a set of uncorrelated components so that the optimal factor/level combination can be found. The PCA is a well-known unsupervised linear technique for dimensionality reduction. The central idea behind PCA is to reduce the dimensionality of a data set consisting of a larger number of interrelated variables, while retaining as much as possible variation present in the original data set. This is achieved by transforming to a new set of variables, the so-called principal components (PCs), which are uncorrelated and ordered so that the first few retain most of the original data variation. It selects a small number of components to account for the variance of original multi-response. Different steps in PCA are discussed as below,

Step (1): Calculation of S/N ratios

$$n = -10\log(MSD) \tag{1}$$

Where, MSD is the Mean square deviation and is calculated as,

$$MSD = \frac{1}{n}\sum y^2{}_i \tag{2}$$

Step (2): Normalization of S/N ratio,

$$X_i^*(j) = \frac{Xi(j) - X(j)^-}{X(j)^+ - X(j)^-} \tag{3}$$

Where

$X^*i(j) =$ Normalized S/N ratio for j[th] quality characteristic,

$Xi(j) =$ S/N ratio for jth quality characteristic,

$X^*i(j)^- =$ Minimum S/N ratio for j[th] quality characteristic in all experimental runs.

$X^*i(j)^+ =$Maximum of S/N ratios for j[th] quality characteristic in all experimental runs.

Step (3): Representation of the multi-response by matrix.

Step (4): Evaluation of Correlation coefficient of normalized multi-response matrix.

$$R_{ij} = \frac{\mathrm{cov}[X_i^*(j), X_i^*(l)]}{\sigma X_i^*(j) \times \sigma X_i^*(l)} \tag{4}$$

Where

$\mathrm{Cov}[X^*i(j), X^*i(l)] =$ Covariance of sequences Xi*(j) and Xi*(l)

$\sigma X^*i(j) and\ \sigma X^*i(l) =$ Standard deviation of sequence Xi*(j) and Xi*(l) respectively.

Step (5): Calculation of eigenvalues and the eigenvectors of the correlation matrix.

Step (6): Computation of Principle Components (PC).

$$p(i)^k = \sum_{j=1}^{m} X_i^*(j) \times v_k(j) \tag{5}$$

Where pi(k) is the k[th] PC corresponding to i[th] experimental run, v_k(j) is the j[th] element of k[th] eigen vector. The total principal component index (TPCI) corresponding to i[th] experimental run (Pi) is computed as follows.

$$p_i = \sum_{k=1}^{m} (p_i k) \times e(k) \tag{6}$$

Where

$$e(k) = \frac{eig(k)}{\sum_{k=1}^{m} eig(k)} \tag{7}$$

Where eig(k) is the k[th] eigenvalue.

Step (7): The TPCI for each experiment run is used to find out the average factor effect at each level. The optimum parameter level that corresponds to the maximum TPCI is predicted.

To validate the application of principal component analysis to multi-objective optimization of MAF process, following case study is considered.

IV. CASE STUDY

MAF is a super finishing process which uses a resilient multi point cutting tool to finish the work pieces. Blend of iron and abrasive particle forms a flexible magnetic brush (FMAB) between the work piece and the magnetic tool. The force exerted by the FMAB on the workpiece is responsible for the finishing action. By varying various process factors the finishing force and torque acting on the workpiece can be varied to finish the work pieces. Knowledge of finishing forces is important in any manufacturing process as the surface integrity of the finished surface is being affected. Fig. 1 shows the experimental setup used for the study. Fig. 2 shows the schematic view of the experimental setup and the directions along which the normal force and the finishing torque act.

This case study analyzes the effect of upper working gap (A), lower working gap (B), abrasive weight percentage (C) and rotational speed (D) on average normal force (F_n) and average finishing torque (T_f). The process factors and their levels considered by Kala and Pandey [5] to perform

experimentation is shown in Table I and the details of the experimental design based on Taguchi L9 orthogonal array and the corresponding average normal and average finishing torque is shown in Table II.

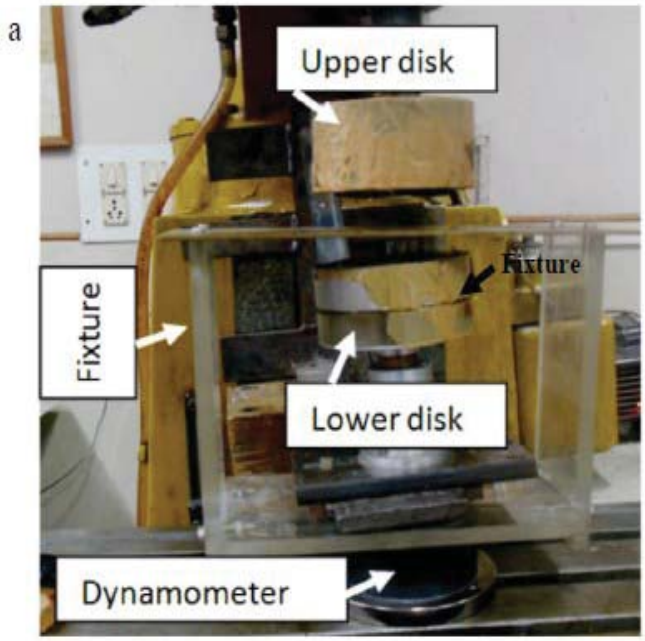

Fig. 1. Experimental setup used in the study [5]

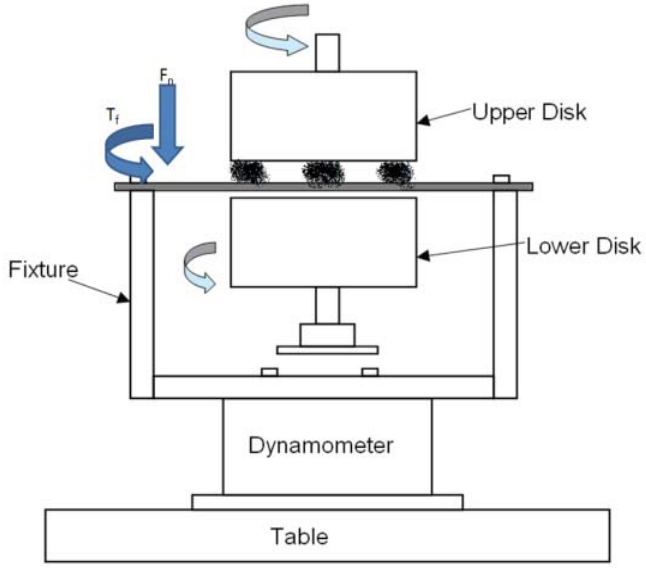

Fig. 2. Schematic representation of the setup used for measuring finishing forces for double disk magnetic abrasive finishing (DDMAF) [5]

TABLE I. PROCESS FACTORS AND THEIR LEVELS CONSIDERED TO PERFORM EXPERIMENTATION [5]

Factors	Description	Levels		
		L_1	L_2	L_3
A	Upper disk working gap (mm)	1.5	2	2.5
B	Lower dusk working gap (mm)	1.5	2	2.5
C	Percentage of abrasive	10	20	30
D	Rotational speed (rpm)	200	300	400

TABLE II. EXPERIMENTAL DATA [5]

Expt. No.	*A*(mm)	*B*(mm)	*C* (%)	*D* (rpm)	F_n (N)	T_f (N-m)
1	1.5	1.5	10	200	72.83	0.425
2	1.5	2	20	300	59.05	0.41

	1.56	1.11	0.42	1.56	1.11	0.42
	0.83	1.28	0.80	0.80	0.83	1.28
	0.80	0.01	0.48	0.01	0.48	0.80
Sum	**3.21**	2.41	1.72	2.39	2.43	**2.52**

In order to have a better understanding of the effect of process factors on finishing force and torque the multivariable regression equations were obtained by Kala and Pandey[5], as given below**.**

$$F_n = 127 - 10.4 \times A - 11.7 \times B - 0.946 \times C - 0.0302 \times D \quad (8)$$

$$T_f = 0.734 - 0.0836 \times A - 0.102 \times B - 0.00651 \times C + 0.00043 \times D \quad (9)$$

Table VI shows the calculation of average normal force (F_n) and average finishing torque (T_f) by using the equation 8 and 9.

TABLE VI. CALCULATION OF FINISHING FORCE AND TORQUE

Sr. No.	*A*	*B*	*C*	*D*	F_n (N)	T_f (N-m)
1	1.5	1.5	10	200	78.35	0.476
2	1.5	2	20	300	60.02	0.403
3	1.5	2.5	30	400	41.69	0.330
4	2	1.5	20	400	57.65	0.455
5	2	2	30	200	48.38	0.253
6	2	2.5	10	300	58.43	0.375
7	2.5	1.5	30	300	46.01	0.305
8	2.5	2	10	400	56.06	0.427
9	2.5	2.5	20	200	46.79	0.225
10	**1.5**	**1.5**	**10**	**400**	**72.31**	**0.562**

Comparison of the results obtained by Taguchi method [5] and PCA are shown in Table VII.

TABLE VII. COMPARISON OF RESULTS

Method	Responses	Optimum Levels	F_n (N)	T_f (N-m)
Taguchi	Finishing force (F_n)	1-1-1-1	78.35	0.476
	Finishing Torque (T_f)	1-1-1-3	72.31	0.562
PCA	Finishing force(F_n)	1-1-1-3	72.31	0.562
	Finishing Torque(T_f)			

Combined index for average normal force and average finishing torque is shown in Table VIII.

TABLE VIII. INDEX FOR COMBINED OBJECTIVE FUNCTION

Responses	Optimum Levels	For F_n	For T_f	Combined Index
Finishing force (F_n)	1-1-1-1	1	0.84	1.84
Finishing Torque (T_f)	1-1-1-3	0.92	1	1.92

V. CONCLUSION

In this study, PCA is applied to multi-response problems, which was solved by Taguchi method. The following are the conclusions

1. PCA results in same optimum level as for the finishing torque and although the value for average finishing force is reduced the extent with which the second objective function is improved is much more, ultimately that results into higher index value for combined objective function. Thus results obtained by PCA are always superior than individual Taguchi method.
2. It is observed that for combined objective function of average normal force and average finishing torque, the upper working gap should be set lower value i.e. at 1.5 mm, lower working gap should be set at lower value i.e. at 1.5 mm, abrasive weight percentage is lower i.e. 10 and rotational speed of the magnet should be set at higher value i.e at 400 rpm
3. Maximum possible value of average normal force and average finishing torque obtained by PCA is 72.31 N and 0.562 N-m respectively.

***Abstract*—In today's scenario of internet world, a cloud computing and data center, a lot of importance has to be given to the security of information while sharing it with different organizations. Present advance data mining techniques gives knowledge about various relationships of itemsets which will be useful to a group of people while enhancing their businesses. However, in many cases the organizations having the source of information may not intended to share such relationships (association rules) with any other organization or they wants to have rights of information. Therefore, there is a need to hide the sensitive information in the database prior to share it among in the organizations. The focus of this work is to understand the hiding methodologies of association rules in database while maintaining the disturbance in the original database as less as possible. However, intended recipients must receive this sensitive information robustly against various intentional or unintentional attacks.**

Keywords— Association Rule Hiding; Privacy Preserving Data Mining

I. INTRODUCTION

Consider the scenario as shown in Fig 1.1. If owner of one of the organizations get an access to the database of the other organization, one can mine the database and able to get the various business secrets (sensitive association rules) of that owner and may result in loss of business. Thus, there is a need of privacy of association rules. There are various ways to achieve this privacy. However, the use of information hiding methodology for this purpose will not only enhance the privacy but also produce minimum side effects (distortion) in the given data base which otherwise creates suspects in the minds of organizations about originality of database. Also, after applying the hiding process to original database, there shouldn't be drastic increase/decrease in the size of database. Ideally, the process of hiding of sensitive association rules should give correct mining results for rest of the association rules and must hide all the sensitive association rules.

An association rule is a rule of type $X \rightarrow Y$, where X and Y are itemsets. If transaction contains itemset X, it (probably) also contains itemset Y.

Agrawal, R. et al. were the first to introduce Association rule mining[1]. Based on the concept of strong rules, Agrawal et al. introduced the problem of mining association rules from transaction data as follows: Let I = {i1,i2,...,in} be a set of n attributes called items. Let D = {t1, t2,..., tm} be a set of transactions called the database. In a database D, each transaction has an unique transaction ID and contains a subset of the items in I. A rule is defined of the form $X \Rightarrow Y$ where $X, Y \subseteq I$ and $X \cap Y = \emptyset$. The sets of items (for short itemsets) X and Y is called antecedent (left-hand-side or LHS) and consequent (right-hand-side or RHS) of the rule. Association rules give the relationships between a set of items in large datasets to be discovered. When we discover such relationships between items, we get a large number of association rules. From these large number of association rules, it is very difficult to conclude which are important one? Then there should be some way or technique or measure which will decide this. By applying this technique we will get the desired or interested association rules. Various interesting measures have been proposed by Geng L., Hamilton et al. [2] and McGarry, K [3]. G. Dong et al. [4], Lallich, S. et al.[5], A.A. Freitas [6], Michael Steinbach [7] also put a focus on interesting measures. Pang-Ning Tan et al. [8] focuses on how to select correct objective measure to find the association rules. Searching for interesting patterns will optimize the problem. To exemplify the concepts, we use a small example from the superstore domain. The set of items is I = {wheat, pulses, rice, spices} and a small database containing the items is shown in Table 1.

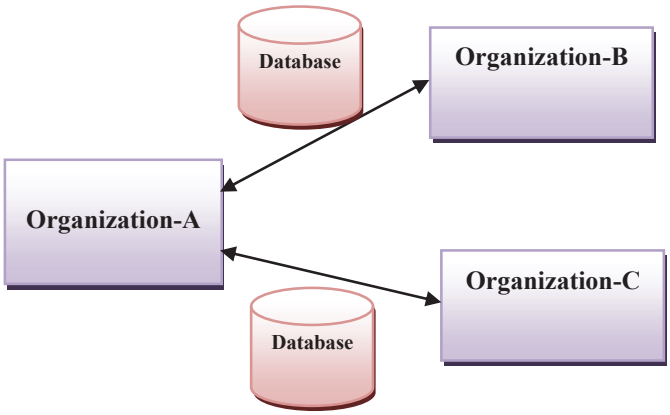

Fig. 1.1 Sharing of database

TABLE I.

Transaction ID	Items
T1	Wheat
T2	pulses, rice, spices
T3	rice, spices
T4	rice, spices
T5	pulses, rice

An example of association rule for the superstore could be {pulses, rice} ⇒ {spices} means if pulses and rice is bought, customers also buy spices. To select interesting rules from all possible rules, constraints on various measures of importance and interest can be used. The best-known constraints are thresholds on support and confidence. The support supp(X) of an itemset X can be defined as the proportion of transactions in the data set which contain the itemset. The support of rule X → Y in data D is given in (1)

$$\text{supp}(X \rightarrow Y) = \text{supp}(X \cup Y) \quad (1)$$

The support is the probability that a transaction contains X ∪ Y. In the example database in Figure 1, the rule {pulses, rice} ⇒ {spices} has a support of 1/5 = 0.2 since it occurs in 20% of all transactions (1 out of 5 transactions). The confidence of rule X → Y in data D is given in (2)

$$\text{conf}(X \rightarrow Y) = \text{supp}(X \cup Y) / \text{supp}(X) \quad (2)$$

The confidence is the conditional probability that transaction contains *Y* given that it contains *X*. For example, the rule {pulses, rice} ⇒ {spices} has a confidence of 1/2 = 0.5 in the database in Table 1, which means that for 50% of the transactions containing pulses and rice the rule is correct.

The association rule mining has many applications. To mention few- shelf management in superstore, sending SMSs to customers when superstores are executing any scheme.

If owner of one of the superstores get the database of the other store, he can mine the database and gets the various business secrets of that owner and may result in loss of business. Thus there is a need to hide association rules. The hiding process should ensure that it will produce minimum side effects. The meaning of side effects is that after applying the hiding process to original database, it shouldn't drastically increase/decrease the size of database, it should give correct mining results, must hide all the required rules.

II. SURVEY

In this section we are going to present the techniques used by the researchers to hide the association rules. The very first heuristic solution to hide association rule was proposed by Dasseni et al.[9]. They proposed three algorithms based on the measures of support and confidence. By using, the confidence measure, an algorithm could decrease the confidence and become insignificant. They looked for the transactions that partially support both the left- and the right-hand side of a sensitive rule. The confidence measure of these transactions is minimized below the confidence threshold.

Oliveira et al.[10] introduced a framework for hiding sensitive association rules. This framework scans the database either once or twice to hide the rules. They select the victim item by computing the frequencies of items in the restrictive association rules. They compute the number of sensitive transactions to hide. Then they are sorting the sensitive transactions by size, and finally hide a sensitive transaction.

Verykios et al.[11] progressed on existing techniques by establishing a distortion and a blocking algorithms. The distortion algorithm works like this- a weight is assigned to each rule in the database based on the minimum confidence threshold is its confidence. For each transaction, based on these weights a priority value is calculated. All the transactions are sorted in ascending order of priority.

Wu et al.[12] proposed an approach that classifies the valid modifications and represents each class by three attributes indicating the modification scheme, the set of items to be contained in the transactions to be modified and the item to be modified.

Sun and Yu [13] [14] proposed a border based hiding process. To have separation between sensitive and nonsensitive items, they suggested a border based approach. Their main aim was data quality. They went for minimization of side effects at the cost of degrading efficiency. An algorithm was proposed to recognize the optimal candidate item to be removed, which has a minimal impact on the border. They used the concept of the weight of a border itemset to count the impact of hiding candidates on the border.

Moustakides and Verykios [15][16] proposed approach efficient than the approach proposed by Sun and Yu. Also hiding quality was better. The proposed algorithms sorts the sensitive itemsets based on their support in an increasing order. The hiding process starts with the sensitive itemset having the minimum support. The procedure is repeated until the hiding of every sensitive itemset is done.

Menon et al. [17] were the first to introduce a Constraint Satisfaction Problem (CSP) to hide association rules. The CSP is formulated as an integer program. The authors proposed two approaches blanket approach and intelligent approach. After hiding one item is remaining from the original transaction in blanket approach. In intelligent approach some of items from the transaction were removed which will result in reducing the

support of every sensitive itemset. The integer program was used to maximize the accuracy of the shared database by minimizing the number of transactions that had to be changed to hide the frequent itemsets corresponding to the sensitive patterns.

Menon and Sarkar [18] improved the first solution methodology. They minimized the number of transactions that need to be sanitized. The authors also tried to keep the minimum number of nonsensitive itemsets lost during the hiding of the sensitive ones. Because of its high complexity, they reported that the problem could not be solved even for very small number of cases. Because of this reason, they proposed a solution that depends on two smaller solutions. First one is sanitization and the modified frequent itemset-hiding. The sanitization solution identifies how the support of sensitive itemsets can be purged from a specific transaction by removing very few numbers of items from it. Because of this fewer nonsensitive itemsets will be lost during the hiding process of sensitive itemsets. The modified frequent itemset-hiding solution will concentrate on minimizing the number of nonsensitive itemsets lost, while hiding sensitive ones.

Gkoulalas-Divanis and Verykios.[19] proposed an exact approach for association rule hiding problem. For effective hiding, the authors revised the border introduced by Sun and Yu [13][14] to find out a minimum set of itemsets without any side effects. They used the revised border to formulate a minimal integer program, which is changed into a binary integer program.

The approach proposed by Gkoulalas-Divanis and Verykios [20] proposed a two-phase iterative algorithm that developed the functionality of the ‘inline’ algorithm. The two-phase iterative algorithm comprises of two phases that iterate until either (1) an exact solution of the given problem instance is identified or (2) a prespecified number of subsequent iterations of the algorithm has been done. The first phase of the algorithm utilizes the ‘inline’ algorithm to hide the sensitive knowledge. If it succeeds, the process is terminated and the modified database is returned. If the first phase is unable to identify an exact solution, the algorithm proceeds to the second phase, in which a certain number of selected inequalities from the CSP of the first phase are removed in an ‘one-to-one’ fashion, until the underlying CSP becomes feasible. The second phase results in the expansion of the positive border, whereas the iteration through the two phases aims to approximate the optimal borderline between the sensitive and public itemsets in the sanitized database.

Gkoulalas-Divanis and Verykios[21] introduced the first exact methodology to hide sensitive frequent itemsets by extending the original database. By utilizing the revised borders as well as the cover relationships among the item sets, authors were able to minimize the set of item sets participating in the CSP, which provides a solution to the sensitive knowledge hiding. The hiding process maximizes the data utility of the sanitized database, with minimum side effects while guaranteeing the satisfaction of all the privacy constraints. The released database (the original and the extended database), can guarantee the protection of the sensitive knowledge, when mined at the same or at a higher support threshold than that used for the mining of the original database. Extending the original database for sensitive itemset hiding has confirmed to offer better solutions for an extended set of hiding problems, compared with the previously presented approaches, as well as to lead to hiding solutions of better quality.

III. PROBLEM STATEMENT

Most of the authors contributed a lot to convert original database into sanitized database to hide association rules but they didn't focus on how to get back the hidden sensitive association rules in intended usage. Also they haven't addressed the attacks by malicious users which are likely to tamper the sanitized database to disturb the hidden sensitive association rules.

Considering the survey in Section II, the main scientific challenges are:

1. How to provide the privacy to association rules?
2. How to categorize and minimize the side effects?
3. How to gain optimality of various data hiding parameters in the scalable database?

Our aim of this research work is to enhance the privacy of association rules of data mining with reduced side effects on false rules, information loss and modification degree by adaptive modification strategies of reversible information hiding in scalable database.

IV. OBJECTIVES

1. To study various association rule hiding methods.
2. To analyze the relationship between various parameters (false rules, information loss, modification) degree with respect to privacy.
3. To measure the performance of existing association rule hiding schemes and to optimize various data hiding parameters while implementing an adaptive data hiding system for robust information hiding of association rules in scalable database.
4. To evaluate and validate the proposed methodology of association rule data hiding and to test the robustness of hidden association rules under intentional or unintentional attacks.

V. PROPOSED METHODOLOGY

1. An extensive literature survey will be carried out to gain the various methods of association rule hiding and analysis of results of methodologies used by previous researchers.

2. Implementation of proposed methodology. Experimentation of proposed algorithm with scalable database to optimize the relationship between data hiding parameters such as false rules, information loss and modification degree to attain privacy as these parameters will be affected while achieving privacy.

3. The overall methodology is described in the following Fig. 1.2 The original scalable database 'D' is used by data mining tool to generate association rules. The selected association rules based on given threshold values of 'Support' and 'Confidence', eventually called Sensitive Association Rules (SARs) are considered while modifying the original scalable database 'D' to draft copy of sanitized database 'DS''. After optimizing various parameters of association rule hiding criterions, the sanitized database will get finalized as '$D^{S'}$'. The embedding function (E) will use a secret key 'K' to convert 'D' to '$D^{S'}$' as:

$$E\ (D\ X\ K) \rightarrow D^{S} \qquad (3)$$

The embedding secret key 'K' will be function of embedding methodology and going to reflect the side information used at the time of embedding and necessary while extracting the original database D. This embedding secret key has to be shared through secured channel for protecting the privacy amongst the trusted organizations.

The intended user will use the same secret key 'K' and extraction function (E-1) to get the original database 'D' as:

$$E^{-1}\ (D^{S}\ X\ K) \rightarrow\ D \qquad (4)$$

4. Various intentional attacks such as addition of noise, filtering and unintentional attacks such as data compression may disturb the sanitized data. However the intended user should get the original data as well as sensitive association rules robustly. Therefore the sanitized data will be tested for its robustness under such attacks. The robustness can be achieved by redundancy in hidden association rules and by adaptively deciding the hidden locations.

CONCLUSION

There are various methodologies of hiding the association rules in the database and optimizing support and confidence. Each methodology has its advantages and disadvantages. The outcome of the proposed research is to hide the sensitive association rules of data mining with following criterions –

i. No false rules generation
ii. No information loss
iii. Modification Degree
iv. Robustness against intentional or unintentional attacks

Apart from above three criterions, the proposed method will be adaptive for scalable database Therefore, the proposed methodology of association rule data hiding will be evaluated and validated with respect to various parameters as mentioned in criterions and also it is necessary to check the satisfaction of above mentioned criterions. The research will implement novel steps to make the proposed system complete in all respect.

***Abstract* – In the present days many illegal activities are taking place in ration shops, which are meant to distribute the commodities to the people who are in below the poverty line, as the distribution process is manually operated and due to which it consumes a lots of time. To overcome this problem we one can use RFID technology. In this paper RFID tags are introduced, The RFID cards are instead of ration cards, which consist of all the details about the card holder like family details, type of card and its validity etc. In this paper we are going to discuss different types of automatic ration distribution system implemented for the automatic ration distribution.**

***Keywords* – RFID, GSM module, Solenoid Control Circuits.**

I. INTRODUCTION

Government of India is issuing Ration Card to every Indian family for fulfilling their daily meal needs. Quantities of different food like rice, sugar, kerosene etc. is fixed for every month per families depending upon their income and total number of person in family. [1] Alongside this Government of India provides different facilities for ration distribution towards poor people but such facilities do not reach up to needy and poor people due to present distribution system. It is mandatory to have a valid ration card to buy the any materials from the ration shops. Presently the distribution process is following a distribution monthly pattern. There is a lacuna for monitoring the unused or balance food material at the distribution centre. And chances of misuse are more due to manual monitoring system. In this paper the solution to the problem of manual distribution system is studied and comparative analysis of three different ration distribution systems is presented. The automated system can be linked with government offices, shopkeeper and the ration card holder. The detailed review of few ration distribution systems which are implemented by using GSM, RFID and PIC Microcontroller is presented.

The remainder of the article is organized as follows. Section II presents the literature survey of different automatic ration distribution techniques and implementations. Automatic ration distribution methods such as automatic distribution system using PLC, automatic distribution system based on ARM7 and automatic distribution system using PIC controllers are described in Section III. Experimentation for automatic distribution system is illustrated in Section IV. Finally conclusions are drawn in Section V.

II .LITERATURE SURVEY

The most of people having the ration card to buy the materials from the ration shop first needs to submit the ration card. They will put the sign on ration card depend on the materials taken they will issue the materials through weighting system with help of human but there are two drawbacks weight of materials may be inaccurate due human mistakes and secondly if any card holder not buy the materials end of the months then shopkeeper buy to other and doing deception.

K. Balakarthik gives the idea under title "Cloud-Based Ration Card System using RFID and GSM Technology" [2]. This paper presents an efficient method for the user to buy the products in the ration shop by just flashing the card at the RFID reader. The user authentication is done by sending a random password text to the user mobile which has to be entered in a keypad. The purchase is validated by the employee only after the details are entered in a windows application which stores the user's personal and purchase information. This paper was published in vol.2, Issue 4, Apr 2013.

Rajesh C. Pingle, P. B. Borole gives the idea about automatic ration distribution system thorough his paper under title "Automatic Rationing for Public Distribution System (PDS) using RFID and GSM Module to Prevent Irregularities", In this automated system conventional ration card is replaced by smartcard in which all the details about users are provided including their AADHAR (social security) number which is used for user authentication. This prompted us to interface smart card reader (RFID Based) to the microcontroller (AT89C51) and PC via RS232 to develop such a system. Using such a system, Government would have all required control/monitoring over the transactions at ration shop. To involve government in the process we proposed connecting the system at ration shop to a central database (provided by government.) via GSM module (SIM900D) and RS232. Hence it is possible to prevent the corruption and irregularities at ration shop. This would bring the transparency in public distribution system and there will be a direct communication between people and Government through this. This paper was published in Volume issue by 2, pp.102-111, Mar 2013. [3]

S. Valarmathy, R. Ramani [4] the idea under title "Automatic Ration Material Distributions Based on GSM and RFID Technology", proposed to use RFID and GSM technology based Ration cards by showing the RFID tag into the RFID reader. Then the controller checks the customer codes and details of amounts in the card. After verification, these systems show the amount details. The customer need to entered the required materials by using the PC, after receiving the materials controller send the information to government office and customer through GSM technology. In this system microcontroller is used for executing the process. This paper was published in vol.2, Issue 4, Apr 2013.

The current public distribution system (PDS) involves corruptions and illegal activities of goods during manual ration distribution process. This is one of the widely controversial issues that grip the wrong information about utilization of material allotted for the card holders. Photo shows the existing Public Distribution System (PDS).

Fig.1.Manual ration distribution at Ration Shop

According to environmental conditions and government rule the prize of material varies and it is different for people according to type of ration card. Many times it is observed that the ration distributers do not disclose the rate chart with proper reference date according to which the rates are decided by government of India. Due to witch consumer are forced to pay as per rate decide by distributers. Figure shows one of the pick from ration shop who does not disclose the dated rate.

India's Public Distribution System (PDS) with a network of 4.78 Lakh Fair Price Shops (FPS) is perhaps the largest retail system in the world [6]. Major problems due to this system are the inefficiency in the targeting of benefits and the resulting leakage of subsidies food grain. The PDS system today supports over 40 Cr. Indians below the poverty line with monthly supply of subsidized food grains.

"55% of the public distribution system (PDS) food grain does not reach the intended people many drawbacks of PDS like PDS leakage, scale & quality issue, system transparency and accountability, grievance redressed mechanism are overcome by making automatic distribution system.

Fig.2. Undated Chart with prize of material in ration shop

III. Methods & Algorithms

The existing conventional ration distribution system has two basic issues one is renewing the ration card every year and corruption by the distributers or by the employees by doing malpractices like diverting food grains to open market to make profit. This can be overcome using automatic ration distribution techniques. The basic fundamental elements of such system are RFID and GSM Technology [3]. Global system for mobile communication (GSM) is a globally accepted standard for digital cellular communication. [2] The RFID reader continuously transmits a 125 kHz carrier signal using its antenna. Such system can be implemented with the different processor such as system using ARM7, PLC & PIC microcontroller.

The Public Distribution System (PDS) in the country facilitates the supply of food grains to the poor at a subsidized price. However, doubts have been raised about the efficacy and cost-effectiveness of the PDS, especially in the light of the growing food subsidy and food stocks. [7]

A. Automatic Ration distribution using ARM 7

In this system LPC2148 (ARM7) plays a vital role of actual processing unit. The 12 MHz crystal oscillator is used to provide the required clock signals to the ARM7. It takes input from power supply of 3.3V for its operation this generation introduced the thumb 16 bit Instruction set providing improved code density compared to previous design .it is versatile processor designed for mobile device and other low power electronics. In ARM7 they are combination of c and assembly language but in ARM7 architecture used more instruction set as compared PIC microcontroller

Disadvantages of ARM7

- Cost is high
- Complex instruction set

- Complicated to designs because number of pin is more

B. Automatic Ration distribution using PLC

An PLC (programmable logic controllers) is an industrial computer used to monitor inputs and outputs depending upon their decisions based on its program or logic (turn on/off) its outputs to automate a machine or process but PLC based automatic ration distribution system have some disadvantages.

Disadvantages of PLC based Automatic Ration distribution

- Difficulty with changes or replacements
- Difficulty in finding errors, requiring skilful work force
- When a problem occurs, hold-up time is indefinite, usually long.
- Cost of PLC is high.

C. Automatic Ration distribution using PIC controller

In PIC based automatic ration distribution system microcontroller plays a vital role. PIC microcontroller is a RISC based Architecture. It is low cost and is used for real time application [7]. The size and cost of the microcontroller are less as compare to PLC and ARM7. The 4 MHz crystal oscillator is used to provide the required clock signals.
As a comparative review study of different method we found that implementation automatic of ration distribution using PIC is best option as compare to others. The block diagram of an RFID and GSM Based Ration Distribution System Using PIC Microcontroller is shown in the Fig.3.This system consists of various parts such as RFID, GSM, microcontroller, motor driver, solenoid control circuits and PC.

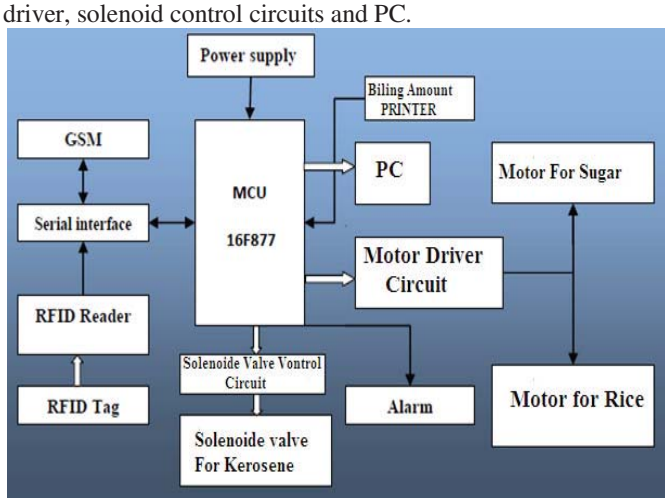

Fig.3. Block diagram of PIC based ADS

Radio-Frequency Identifications (RFID) is small electronic device that consist of a small chip with antenna. The chip is typically capable of carrying about 2,000 bytes of data. RFID has significant advantage of above the others devices, RFID device does not require to be found accurately relative to the scanner. The RFID devices will work within a 10 meter (up to 20 feet for high-frequency devices) of the scanner. The other device called RFID tag is used to read information about the customer through RFID reader. The GSM used to send the SMS to the customer as well as government authorized person for the verification of customer details, material prices, baling of materials and amount of material sanction by government according to type of ration card. Second important part of implementations is visual basic tool. Visual Basic is a tool that allows you to develop Windows (Graphic User Interface - GUI) applications. The applications have a familiar appearance to the user. GSM also plays an important role in this system GSM offers wide range of services like voice, data and internet access.[9] GSM is a low cost mobile communication used by the user to activate ON/OFF control remotely. [12] Fig.4 shows the basic flow of operation of Automatic Ration distribution using PIC controller

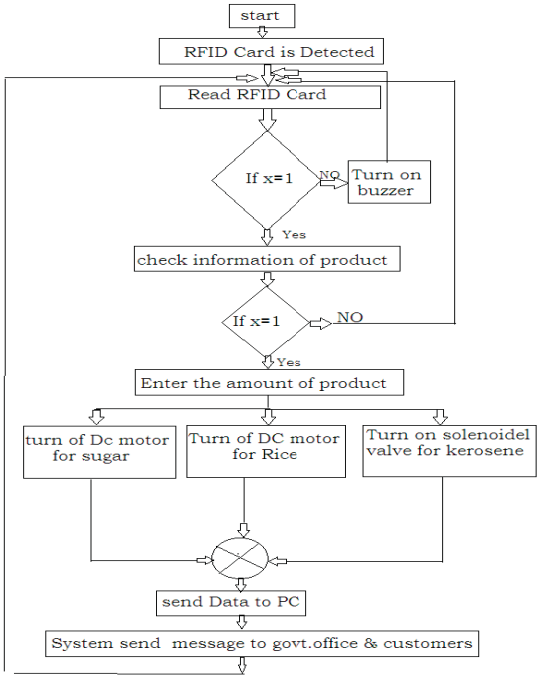

Fig.4. Flow chart of ARD System using PIC

1. Initialization of process
2. Check the tag, it is valid or not.
3. If the card is invalid card then display it as an invalid card by activating the buzzer.
4. Else if the card is valid then go to the next step.
5. Check the type of card either it is a yellow card or white card.
6: If the card detected by the reader is a yellow card then display the card holder's details on the PC screen.
7. Based on type of material chosen, the motor or solenoid valve is activated.
8. The load cell or level indicator is checked for proper quantity.

9. After collecting proper quantity material motor or solenoid is disabled.
10. GSM module will send the information in form of SMS to the user as well as PDS authority.
11. Current stock in the ration shop is displayed using PC

Advantages of PIC microcontroller

- Supports up to 32 Endpoints. (16 bidirectional)
- On-Chip USB Transceiver with On-Chip Voltage Regulator.
- Four Timer modules (Timer0 to Timer3).
- Dual Oscillator options allow microcontroller and USB Up to 2 Capture/Compare/PWM (CCP) modules
- High Performance RISC CPU Synchronous Serial Port (SSP) with SPI (Master mode) and I2C™ (Master/Slave)

IV. EXPERIMENTATION

From the above review study we wish to implement an system which is design to distribute ration material automatically so as to reduce man power as well as to control the corruption in ration distributions which is to be design should be capable of identification of users information and the amount of material allotted to him according to type of card issued by the government of India. Hardware includes the controlling unit, RFID tag, material storage, automatic billing system. Most important is GSM so as to provide legal data information to GOV of India.

V. EXPECTED RESULTS

The expected results from the system is the system should have a display which shows the following information on screen when RFID card is inserted by the customer.

User 1
Card no. 8975538244
Available material in ration shop
Rice- 100kg, Oil- 50litre, wheat-200kg
Allotted material: Rice- 5kg, Oil- 5 liter wheat-20kg

If the card is Invalided the system should shows the massage on screen as

User 2
Invalid ID

After purchasing the material allotted to the customer the massage should be deliver which includes details of bill and amount to be paid to distributor.

User 1
Card no. 8975538244
Allotted material: Rice- 5kg, Oil- 5 liter wheat-20kg
Material parches: Rice- 2kg, Oil- 2 liter, wheat-10kg
Delivered material-: 12:36pm, 05/10/2015
Total amount to be paid = Rs. 320
Balance Material: Rice- 3kg, Oil- 3 liter wheat-10kg
Available material in ration shop
Rice- 98kg, Oil- 48litre, wheat-190kg

Automatic bill should be generating after confirmation and the database should be auto update after every customer. Figure 5 shows the expected format of auto generated bill. The rates includes in bill are not actual but we expect the rate according to the governments norms. The note should be given at the end of bill which gives the idea about rate of material and related circler pass by government of India or by state government.

Distributor : 126589 **Date: 05/10/2015**

Sr. No	Material	Quantity	Rate	Amount
	Rice	2 Kg	30	60
2	Oil	2 lit	30	60
	Wheat	10 Kg	10	100
			Total	220

Note: Rates of all the materials are according to government circular it may change.

Fig.5. Expected format of auto generated bill at PSD

VI. CONCLUSION

In this paper comprehensive survey of present day automated ration distribution system is presented. The problem of existing manual ration distribution system with unusual and uneven distribution is addressed through appropriate and relevant literature. The outcome of the survey focuses on the significant issue for the sleaze in ration distribution and inappropriate or incorrect data of quantity arability at distribution center. The solution suggested in the survey for quantitive analysis of material at the distribution center. Another issue is up gradation of ration card is also discussed. As the up gradation process is quit complicated people use to continue the same card even if number of people on the card changes due to some reasons. Hence from the above study we conclude to have Automatic Ration Distribution System which overcomes all the issues stated earlier. System must be easy to install and should be economical in favor of GOV of India. It is further believed that the survey carried out in this paper can be beneficial for design and development of automatic distribution system for benefit of the needy people.

Abstract*— Future mobile communication networks (MCNs) are expected to be more intelligent and proactive based on new capabilities that increase agility and performance. However, for any successful mobile network service, the dexterity in network deployment is a key factor. The efficiency of the network planning depends on how congruent the chosen path loss model and real propagation are. Various path loss models have been developed that predict the signal propagation in various morphological and climatic environments; however they consider only those physical parameters of the network environment that are essentially static. Therefore, once the signal level drops beyond the predicted values due to any variance in the environmental conditions, very crowded areas may not be catered well enough by the deployed network that had been designed with the static path loss model. This paper proposes an approach that incorporates the environmental dynamics factor in the propagation model for intelligent and proactively iterative networks.

Keywords—Dynamic Path Loss Model; Friis Path Loss Model; Okumura-Hata Model; COST 231 Hata Model; Intelligent Networks.

I. INTRODUCTION

In any Transmitter (T_x) and Receiver (R_x) system, the power received at the receiver end is subject to the environment composition through which the EM wave propagates from T_x to R_x. The role of any path loss model is to predict the expected values of the received signal level in absentia of T_x-R_x deployment. Therefore, such models are very crucial for network design and optimization strategies.

A. Crowd and Coverage

A lot of work has been done to manage the coverage in a dense crowded environment. Some incorporate the deployment of additional equipment such as the femto-cell in the high subscriber areas as discussed in [2] (whereas other propose serving the area though an alternative approach, such as unmanned aerial vehicles (UAVs)[3], [4], and [5]. Other research focuses on the services and applications that are crowd dependent by means of crowd sensing of the user density [6]. However, these solutions are subject to instantaneous conditions of the subscriber crowd.

B. Why gathering is problematic?

An accurate pathloss model can save loss of capital and operation expenses by avoiding over or under equipment requirements. However, existing path loss models do not consider the time-varying compositions of the propagation environment and presume the environmental characteristic as predominantly static. Therefore, in the cases when the time varying components deviates significantly, the network performance fails to perform optimally. One of the majorly occurring events is the crowd burst and accumulations.Previously published work [1], discussed the effect of the crowd on the capacity demand of the Area in Question (AiQ), which was termed as 'Place Time Capacity.' In this paper, we study the impact of the network coverage and the significance of the evolved equations. The discussion is not only limited to "human" density but any entity that may vary in numbers and can affect the electromagnetic wave (EMW) propagation.

This paper is structured as follows. Section II surveys the common current propagation models and reasons they cannot cater for the specifics of the dynamic environments. Section III proposes an accommodative path loss model. Section IV proposes a verification of the concept through an empirical approach (experiment).Section V concludes the paper.

II. STATIC PATHLOSS MODELS

For a network deployment, the size of cells and the proposed locations of the respective base stations (BSs) are predicted by path loss model. Figure 1 shows several propagation scenaria[7], [8]. The common parameters used in the path loss models associated with the propagation scenario in Figure 1, are summarized below:

- λ : Operating Carrier Wavelength of the signal,
- f : Operating Carrier frequency of the signal,
- T_x : Antenna of the Transmitting Module,
- R_x : Antenna of the Receiving Module,
- D : Distance between T_x and R_x,
- P_t : Power Transmitted from a T_x,
- P_r : Power Received by a R_x,
- G_t : Gain of T_x,
- G_r : Gain of R_x,
- h_t : Height of T_x with respect to ground,
- h_r :Height of R_x with respect to ground,
- PL(D):Total Path loss at a distance D from T_x

A. Definition of Path loss

Path loss [9], can be expressed in the terms of least square (LS) regression as in (2):

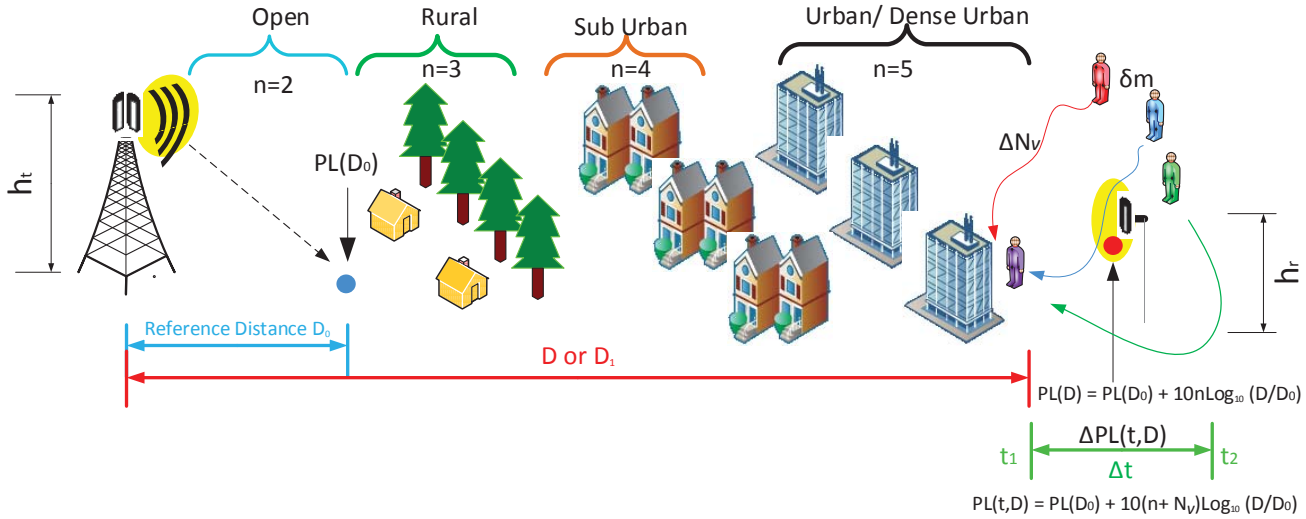

Figure 1: Factors Affecting Propagation of Signal.

$$PL(D) = PL(D_0) + 10n\log_{10}\left(\frac{D}{D_0}\right) \quad (1)$$

Here, D_0 is the reference point, which is usually obtained by empirically measuring the signal values at a unit distance from the transmitter (1km for outdoor large cell environment and 1m for indoor or pico cell environment). Usually, for a reference measurement, there is free space between Tx and Rx. The path loss exponent "n" represents the environment, in which the prediction needs to be done. For free space propagation medium between T_x and R_x, n=2 that gradually increases to 3 for flat rural, 3.5 for rolling rural, 4 for suburban, and, 4.5 for dense urban and so on.

B. Popular Pathloss Models

1) Friis Path Loss Model

The Friis path loss model [10] is the free space model that considers the loss of signal strength due to the distance between transmitter and receiver and the respective gains as mentioned below:

$$\frac{P_r}{P_t} = G_t G_r \left(\frac{\lambda}{4\pi D}\right)^2 \quad (2)$$

2) Okumura-Hata Model

Okumura- Hata [11] is one of the most rigorously used urban terrestrial propagation models for large-scale deployments:

$$P_r = P_t + G_t - 69.55 - 26.16\log_{10}(f) + 13.82\log_{10}\left(\frac{h_t}{h_0}\right)$$

$$+C(h_r) - \left[44.9 - 6.55\log_{10}\left(\frac{h_t}{h_0}\right)\right]\log_{10}\left(\frac{D}{D_0}\right) + A_\alpha$$

(3)

Where,

- A_α: Area adjustment factor,
- $C(h_r)$: Receiver antenna height correction factor,
- h_0 : BS antenna height (length) =1m,
- D_0 : Reference distance = 1 Km.
- L_{50} : Median path loss between Tx and Rx,
- L_{FS} : Free Space Path Loss,
- A_{mu}: Attenuation due to propagation in densely structured environment,
- H_{tu} : T_x antenna gain factor,
- H_{ru} : R_x antenna gain factor,

3) Cost-231Hata Model

The Cost-231 Hata Model [12]is given by (4) (in dB):

$$PL_{cost231} = 46.3 + 33.9\log_{10}(f) - 13.82\log_{10}(h_t) - aH$$

$$+\left(44.9 - 6.55\log_{10}(h_t)\right)\log_{10}(D) + C_E \quad (4)$$

Where, aH and C_E are environment dependent (Urban, rural, etc. values).

These models are inevitably static in nature and incorporate the morphological properties of the Area of Interest (AoI) such as vegetation, water bodies, concrete, etc. Therefore, these propagation models do not include environment dynamics.

Each model that has been developed is the result of the empirical fine tuning of the base path loss models through exhaustive On-field measurements. Hence, theoretically, a static user at a constant distance from the base station must experience the same signal strength for the entire duration till user resides at that distance. However, there are significant variations in the signal levels even though T_x and R_x are static in the Area of Interest (AoI).

The radio environments, investigated under macroscopic level may not show significant importance to this time-dependent variations and are comfortable in the static modeling of the radio propagation. However, future networks shall be extremely environmentally sensitive and dynamic environments may affect the performance significantly.

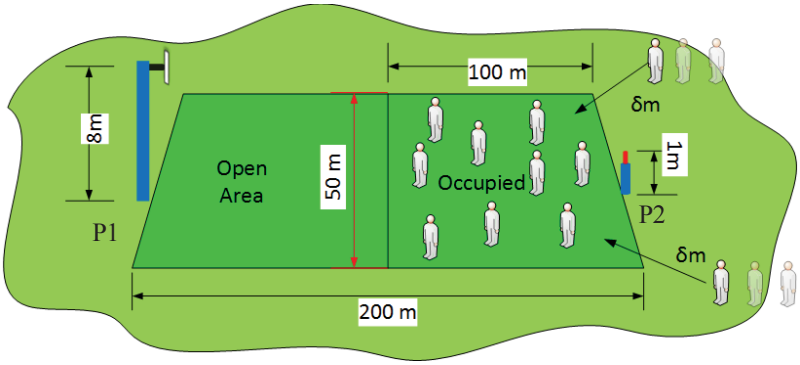

Figure 2: Study of People's Accumulation in Network Environment

Moreover, these networks will be more intelligent, and the near future may see those incorporating self-configuring properties regarding parameters and positions. In such cases, the static propagation model may not provide sufficient information for the intelligent networks to respond to the variation in the network environment and inclusion of the environmental dynamics in the path loss equation.

III. Dynamic Path Loss

Let us assume that a mobile user is static at a distance D_1 from the base station (see figure 1) which means that as per propagation model, the user at a distance D_1 must experience an unchangeable loss given by (see equation 1):

$$PL(D_1) = PL(D_0) + 10n\log_{10}\left(\frac{D_1}{D_0}\right) \quad (5)$$

Let us also assume that the user observes the signal level at the receiver end between the time intervals $[t_1, t_2]$. Incorporating this assumption in (5), we have:

$$\Delta PL(D_1)\Big|_{t_1}^{t_2} = \Delta PL(D_0)\Big|_{t_1}^{t_2} + \Delta 10n\log_{10}\left(\frac{D_1}{D_0}\right)\Big|_{t_1}^{t_2} \quad (6)$$

With all the relevant physical parameters static for this time interval, the terms in the right-hand side (RHS) of (6) reduce to zero, which means, $\Delta PL(D_0)\Big|_{t_1}^{t_2} = 0$, and,

$$\Delta 10n\log_{10}\left(\frac{D_1}{D_0}\right)\Big|_{t_1}^{t_2} = 0 \quad (7) \quad (8)$$

Therefore, from 6,7, and 8 we have:

$$\Delta PL(D_1)\Big|_{t_1}^{t_2} = 0 \quad (9)$$

This means that theoretically, the user does not experience any variation in the path loss. However, in reality this is not true, and the user does experience significant variations in the signal level which is not incorporated by the path loss models. Therefore, (9) is not true and the inequality can be written as:

$$\Delta PL(D_1)\Big|_{t_1}^{t_2} \neq 0 \quad (10)$$

In Figure 1, T_x and R_x are placed at positions P_1 and P_2, respectively, in the AoI. Rewriting equation (1) in non-logarithmic form, we have:

$$PL(D_1) = PL(D_0)\times\left(\frac{D_1}{D_0}\right)^n \quad (11)$$

Where, $PL(D_0)$ is the path loss measured at the reference distance D_0 from the T_x and is given by:

$$PL(D_0) = \left(\frac{4\pi D_0}{\lambda}\right)^2 \quad (12)$$

Where, D_1 is the distance of user receiver (R_x) from T_x (See figure 3). In case the environment between T_x and R_x is free space, the path loss exponent "n" takes an inevitable value n=2 and (11) reduces to:

$$PL(D_1) = \left(\frac{4\pi D_0}{\lambda}\right)^2 \times \left(\frac{D_1}{D_0}\right)^2 = \left(\frac{4\pi D_1}{\lambda}\right)^2 \quad (13)$$

Initially, there is a free space environment between T_x and R_x. However, the medium between them gradually densifies in small increments of "material" δm. This material may be of any kind such as metal, glass, concrete, or even humans. Now, let this small incremental material δm enters the AoI. Then, as discussed in Section I, the value of n must experience an increment from the static condition, even if it is a very small increment. Therefore, in such a case, the static path loss also experiences an increment and becomes a time dependent function. Therefore, from (11) and (12), this time dependent path loss behavior can be expressed as:

$$PL(D_1,t) = \left(\frac{4\pi D_0}{\lambda}\right)^2 \times \left(\frac{D_1}{D_0}\right)^{n+N_V(t,m)}$$

Or,
$$PL(D_1,t) = \left(\frac{4\pi D_0}{\lambda}\right)^2 \times \left(\frac{D_1}{D_0}\right)^{n} \times \left(\frac{D_1}{D_0}\right)^{N_V(t,m)} \quad (14)$$

Where, $\widehat{PL}(D_1,t)$ is the time dependent path loss at distance D_1 and at time t_1. The $N_v(t,m)$ is a variable defined as the Variant Path Loss Exponent and is the material and time dependent function that incorporates the time dependent variances in the network environment. The value of N_v at a timet defines the additional path loss due to amount of dynamic material at time t. As D_0, D_1, and n are constant, (14) can be written as:

$$PL(D_1,t) = K(n,D_0,D_1)\times\left(\frac{D_1}{D_0}\right)^{N_V(t,m)} \quad (15)$$

Where, $K = K(n,D_0,D_1) = \left(\frac{4\pi D_0}{\lambda}\right)^2 \times \left(\frac{D_1}{D_0}\right)^n$, (16)

and is time independent variable.

Therefore,

$$\frac{d}{dt}PL(D_1,t) = \frac{d}{dt}\left\{K\left(\frac{D_1}{D_0}\right)^{N_V(t,m)}\right\} \quad (17)$$

or, $$\frac{d}{dt}PL = K\frac{d}{dt}\left(\frac{D_1}{D_0}\right)^{N_V} \quad (18)$$

As we know that for any variable x and constant a,

$$\frac{d}{dx}a^x = a^x \log_e(a) \quad (19)$$

From (18) and (19) we have:

$$\frac{d}{dt}PL = \left[K\left\{\log_e\left(\frac{D_1}{D_0}\right)\right\}\left(\frac{D_1}{D_0}\right)^{N_V}\right]\frac{d}{dt}(N_v)$$

or, $$\frac{d}{dt}PL = \left[\dot{K}\left(\frac{D_1}{D_0}\right)^{N_V}\right]\frac{d}{dt}(N_v) \quad (20)$$

Where, $\dot{K} = K\log_e\left(\frac{D_1}{D_0}\right)$ (21)

As discussed before, N_v is time and material dependent variable. Therefore,

$$\frac{d}{dt}(N_v) = B(m)\frac{d}{dt}(m) \quad (22)$$

Where, B(m) is the Base Variance that depends on the type and concentration of the material. The term $\frac{d}{dt}(m)$ defines the rate at which the material densifies or rarifies in the AoI. Substituting (22) in (20), we have:

$$\frac{d}{dt}PL(D_1,t) = \dot{K}\left(\frac{D_1}{D_0}\right)^{N_V} B(m)\frac{d}{dt}(m) = \dot{K}\left(\frac{D_1}{D_0}\right)^{N_V} B(m)m' \quad (23)$$

In the case when the incremental variation in material density is due to the movement of the material entities, the term m' represents velocity $v(t)$ of the incremental entity times the volume density of the material defined as ρ_m. Therefore, (23) can be rewritten as:

$$PL'(D_1,t) = \dot{K}\left(\frac{D_1}{D_0}\right)^{N_V} B(m)\rho_m v(t) \Rightarrow PL' = \dot{K}\left(\frac{D_1}{D_0}\right)^{N_V} B(m)\rho_m v \quad (24)$$

Therefore, in the case when the material density is uniform, and the properties are not time dependent, $\widehat{PL'}$ will be a constant gradient and drop in the received signal level with be linear in the logarithmic domain.

IV. EMPIRICAL APPROACH

Rewriting (14) in dB format, we have:

$$PL_{dB}(D_1,t) = 10\log_{10}\left\{\left(\frac{4\pi D_0}{\lambda}\right)^2 \times \left(\frac{D_1}{D_0}\right)^{n+N_V(t,m)}\right\}$$

Or simply,

$$PL_{dB} = 10\log_{10}\left(\frac{4\pi D_0}{\lambda}\right)^2 + 10\log_{10}\left\{\left(\frac{D_1}{D_0}\right)^{n+N_V(t,m)}\right\} \quad (25)$$

From (12) and (25), we have:

$$PL_{dB} = PL_{dB}(D_0) + 10(n + N_v(t,m))\log_{10}\left(\frac{D_1}{D_0}\right) \quad (26)$$

Where, $PL_{dB}(D_0)$ is a dB representation of (9). Hence,

$$PL_{dB} = PL_{dB}(D_0) + 10n\log_{10}\left(\frac{D_1}{D_0}\right) + 10N_v(t,m))\log_{10}\left(\frac{D_1}{D_0}\right) \quad (27)$$

As we know from (5) that:

$$PL(D_1) = PL(D_0) + 10n\log_{10}\left(\frac{D_1}{D_0}\right)$$

Therefore, from (5) and (27) we have:

$$PL_{dB} = PL_{dB}(D_1) + 10N_v\log_{10}\left(\frac{D_1}{D_0}\right) \quad (28)$$

The equation (28) is a standard line equation known as:

$$y = gx + C \quad (29)$$

The equation 28 means that in logarithmic scale, the received signal will experience a linear drop when there is an increment in the density of the material with constant velocity, and material property does not vary with time and space keeping $B(m)\rho_m$ as constant.

To verify the mathematical model in (28), we conducted an experiment as shown in Figure 2. We selected an area of 200X100 meters in dimension from a large open ground (in Goa, India). Points P_1 and P_2 were chosen for placing T_x and R_x respectively (see figure 2). For other parameters related to the setup, please see figure 2. Firstly, the measurement was taken as free space and then people were allowed to enter in the one-half of the area. People entered the area in steps of 10,50, 100, 200, …, 1000 and signal measurements at P_2 were recorded for a duration of 20 minutes for each step. To avoid the interference from other mobile and point-to- point services, we selected a band of 1400MHz that is currently not being used for terrestrial mobile services in the selected rural areas of India. All power values are in [dB], frequencies are in [MHz] and distances are given in [m].

Figure 3 shows the significant and consecutive discrete drops in the received signal level from the receiver placed at P_1. This drop is observed for the entire duration (20 minutes or 1200 seconds) of the measurement for each set of groups of people, which means that this drop is not because of the instantaneous disturbances but due to the people gathering in the area between the T_x and R_x path.

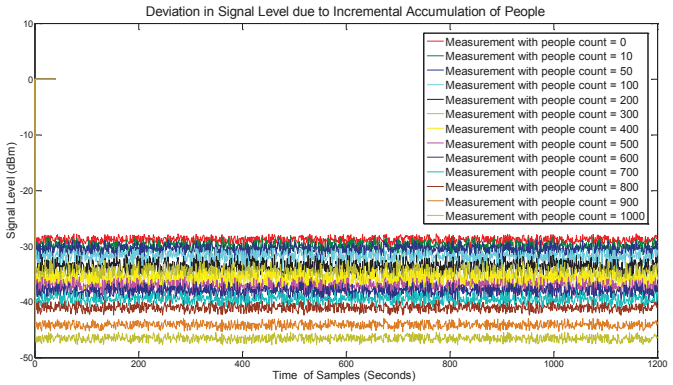

Figure 3: Received Signal Drop v/s Time (Per People Density)

Figure 4: Received Signal Drop v/s People Density

During the measurements, people were allowed to fill the path as evenly as possible by roaming in the area. Out of 1200 received signal values recorded for each group, we randomly selected measurement values at the 100th second for each group to create a data set of signal level versus people's accumulation. This data set is plotted as shown in Figure 4.Itcan be clearly seen that the drop in observed signal levels follows the regression line y=78x-29. Similar observations were made for other data sets at different times. This empirical observation also corresponds to the equation that we have derived in (29).We see that data points deviate from the regression line. This is due to other factors playing during the measurements such as Fresnel Radius, multipath losses and ground reflections, etc. that are not incorporated in the basic path loss model for the ease of representation. We also bring this to notice that the people's density was not high enough to make δm infinitesimally small so that the impact of granularity can be avoided.

V. CONCLUSIONS

In this paper, we have discussed the path loss variability due to non-static elements, (i.e., materials), entering the path between the T_x and R_x. We incorporated this time-dependent variation in the path loss model as in equation (1) equation though some assumptions and then mathematical derivation. We have introduced a Variant Path Loss Exponent (N_v) in the PL equation as in equation (1) that accommodates these instantaneous variations. Lastly, we verified this derived equation through an empirical observation that was made by signal measurements carried out when people gather in an area from 0 to 1000 in certain defined steps.

VI. FUTURE WORK

The variable path loss model $\widehat{PL}(D_1, t)$which is derived in this paper will be very useful for the intelligent networks performing in extreme dense net environments. The variability factor Nv can be used to "train" the "intelligent networks" to behave with the varying propagation environments. We have discussed the impact of people accumulation on capacity dimensioning in[1], the proposed model incorporates coverage aspect of the dynamic network environment. Further, this model has huge scope for further studies and its suitability to the intelligent network environment. This concept can be useful in the analysis of the margins for senstivity of the radio equipments that will be designed to serve the extremely congested and dynamic network conditions.

"IoT" based Smart Village

An Indigenous step towards 'Digital India'

Madhukant Patel (MD, Reve Automation LLP, Former Scientist Engineer, ISRO, PhD Scholar UPES, Dehradun)

Piyush Yadav (Director, Green Cloud iSoft P. Ltd., MBA from University of St. Gallen, Switzerland)

Abstract:
With a strong vision and drive of Digital India, the first deserving audience to target is Rural India. From Darwin's day, mankind has seen the evolutions and revolutions. Each time, society has seen the changes which are affecting the way society functions. With advancement of technology and political will, the transformation is in rapid momentum and going to achieve much different milestones in terms of livelihood of rural India. The rural world has seen the dynamism of changes through means of scientific & technological revolutions, economical revaluations, green revolutions, educational effects and many more. At present, the world is experiencing the revolution in telecommunication, data communication, cloud computing and smart mobile devices. This dynamism has changed the face of urban and rural life all across. Urban areas seem to be more inclined to accept and adopt Information and Communication Technology due to advantages of literacy and better infrastructure as compared to rural areas. Such suitable circumstances of urban scenes throws great measure of achievement of this innovation as unmistakable as savvy urban areas and better occupation of residing human beings. But the problems, consequences and opportunities in urban territories are distinctive for successful use of Information and Communication Technology for reasonable improvement of provincial masses. The present research on 'rural echo system' done by our group companies is focused into the frame work or backbone for smart villages and smart cities using IoT (Internet of Things) for all segments of life; may it be comfort, safety, energy efficiency or monitoring control of functions connected with villages. The concept of "Smart Village" is to connect every individual and homes with each other and to connect them with their farms, dairies, APMCs, trade links, dispensaries, schools and governance in general. The framework will also support and spot neighbourhood business opportunities, enhancing wellbeing and welfare, improving just engagement general upgrade of rustic town inhabitants. The " Smart Village " concept aims to realize its goal through providing policymakers with insightful, bottom–up analyses of the challenges of rural development. The presentation will be accompanying live demonstration of "IoT enabled rural ecosystem".

Keywords: ***IoT (Internet of Things), IoE (Internet of Everything), Rural Eco-cycle, Smart framework, Smart sensors, Informatics, Access points, Smart HUB, Cloud Computing, APMCs***

Introduction:
As per our understanding, Internet is a network of networks that consists of millions of private, public, academic, research, business, and government networks, of local to global scope, that are linked by a broad array of electronic, wireless and wired networking technologies. Internet of Things is making an open and comprehensive network of intelligent objects that have the capacity to auto–organize, share information, data and resources, reacting and acting in face of situations and changes in the environment. Internet of Things is the latest advancement in Information and Communication Technologies, providing global connectivity and management of sensors, actuators, devices, machines, users and informatics. Things are also often interchanged with the word "Objects". IoT can be defined as "things belonging to the Internet" to supply and access all of real-world information. IoT is the biggest promise of the technology today, but still lacking a novel mechanism, which can be perceived through the lenses of Internet, things and semantic vision. Internet of things is widening to evolve as Internet of Everything (IoE).

The Internet carries an extensive range of information resources and services, IoT is the convergence of Internet with Smart sensor and Smart objects. Realizing the vision of sustainable smart city applications requires enhancing IoT technologies with new ways that will enable things and objects to become more reliable, more resilient, more autonomous and smarter. The Internet is a powerful global communication medium that provides instantaneous information across geographical, cultural, language, and time spheres. 'Thing' can be defined as an entity, an idea, a quality perceived, or thought to have its own existence in the world.

The IoT is a technology and their integration is to be implemented in Indian villages to achieve near to ideal ecosystem of a typical Indian village.

Ecosystem of typical Indian village
From ancient days, Indian villages have an 'autonomous' and self-governing system. The 'Panchayat raj' was precisely defined on this concept.

Following are the key factors to form typical Indian smart village ecosystem:

1. Education
   a. Schooling: Teachers training, quality delivery to students, attendance, effective and real-time feedback mechanism, providing general awareness about opportunities and challenges to students, making aware about local, national and international dynamism, informant of effective & efficient evaluation system, continuing motivations are few of the parameters where the present system is lacking. e-Learning, distance-learning, lab and hands-on methodology through physical and virtual laboratories, etc. are supported by smart sensors and smart framework. Adult education system can be easily augmented on the smart framework.
   b. Vocational: In recent past, the rural people (illiterate and semi-literates) have shown good amount of innovations. Through digital media and smart framework, variety of vocational trainings like crafting, carpentry, poetry, goldsmith, fabric based art, singing, dancing etc can be easily taught using modern teaching aids. Providing knowledge on trade and business aspects can motivate them and ultimately lead them to sustainable self-employment by connecting Government trade linked system.

2. Health and Medical Emergencies:

Regular and emergency health support system is lacking in villages. Using smart sensors and smart framework, each village person can be linked with primary health centres as well as 24x7 medical assistance and monitoring can be done by expert doctors working in cities. The system also supports online prescriptions and provides alerts for regular health check-up awareness, camps and follow-up from digital data (data mining).

3. Agriculture and Farming:

The biggest challenge for Indian villages is to automate agriculture, farming, irrigation, watering of plants, establishing green houses and harvesting systems. The smart system can monitor life of crops and qualifies agro products that have link with APMCs.

4. Animal Husbandry:

Animal husbandry is one of the resource to create economic reforms of village and provides regular health check-up of animals and creates eco-system in production from animal related products.

5. Rural Transport:

The smart transport is digitally linked with private and government transport service providers through e-ticketing window and booth. The system has IoT displays to show timing and schedule of local transport vehicles.

6. Governance (PUNCHAYAT):

The system has facility to lodge online complaints & grievances and is able to resolve with digital link with state & central government reporting system. Whole lot of forms and certificates may be requested through smart devices through IoT infrastructure.

7. Sahakari Mandali Reforms:

All Sahakari Mandalis have Internet working facility and are able to exchange and broadcast information. The system itself handles conferences and trainings. The economic reforms are possible to provide online trading for products. Through smart village tools and means, Sahakari can link each farmers/ members through infomatics; enabling people with handy information and alerts from time to time.

8. Energy:

The power generation and distribution network can be created for domestic, farms, hospitals, dairies and other amenities. Using smart framework and smart sensors, people can save/ optimise the energy usage by minimising wastages.

9. Eco-enterprise and self-employment:

By providing data and support, the rural people can be motivated for self-employment. The system can also help the individual to form a cluster and strengthen them to compete and venture into larger territories.

10. Natural Calamities:

The system advances to exchange and broadcast information for floods, earthquakes, fires and others to save humans and their belongings.

Literature survey:
Internet of Things and Smart Things has been going on for more than a decade and reaches back to original dream of ubiquitous computing. Recently popularized the idea of Smart Objects and the IoT, Smart Things is another paradigm shift in IT world. Smart Things are the things that are having embedded smartness or intelligence, identification, automation, Monitoring and controlling calibre. Smart Things are assisting human life a lot, nowadays without their applications life is becoming cumbersome. Systematically on Internet, Things, and then explores on Internet of Things and finally Smart Things from researchers', and corporate's Perspective. This things forward towards the Smart Things and its applications. This in turn would help the new researchers, who want to do research in this IoT

domain [1].

For the smart village we can use the existing idea of the smart city. As an example, the existing smart city application of heat and energy management. In a world of multi-stakeholder information and assets provision on top of millions of real-time interacting and communicating things, systems based on IoT technologies aim at exploiting these assets in a resilient and sustainable way allowing them to reach their full potential. The heat management aims to utilizing different resources (such as heat and electricity meters) in order to optimize use of energy in commercial and residential areas. The energy management for the cruise control of public transportation, and aims at utilizing different resources (such as environmental and traffic Sensors) in order to provide driving recommendations that aim at eco efficiency [2].

For the smart villages creating perfect business environment where work meets pleasure, using the latest technology "Internet of Things" in operational support and infrastructure, Internet of Things, in short IoT, can impact Governance. Internet of Things and Smart Services will change Society. SMART VILLAGE will become the hub of business community and the economic growth. The Internet of Things is driven by an exponential expansion of the Internet through the inclusion of physical objects combined with an ability to provide smarter services to the environment as more data becomes available [3].

Smart Villages are the need of the hour as development is needed for both rural and urban areas for better livelihood and Information technology will offer an effective solution. There are successful technologies available, which have been implemented in urban areas. There is tremendous pressure on urban landscapes due to migration of rural people for livelihood. Smart Villages will not only reduce this migration but also irrigate the population flow from urban to rural area. Smart village concept will have potential to uplift the grass-root level of the country, hence adding feather in the overall development of India [4].

Failure to utilize Information Technology tools for rural development is because of lack of strategy, unfocused planning, monitoring and execution of the activities. All these activities need to be addressed based on the varying rural situations. A specially designed suitable framework for rural areas on the grounds of Science, Technology, Engineering, Regulations and Management will play important role to build next generation smart villages. Each village is a unique example and having diverse set of problems and situations. It may be difficult to implement the same model of village development for all the villages. To address this complex problem, Public Private Partnership (PPP) may play key role for developing smart villages. Benefits of the smart village efforts are foreseen to be tremendous.

Problem Formulation:
To develop an ideal ecosystem in Indian village to provide services, alerts and interactive data exchanges & analytics based on the query messages to satisfy all needs of the citizens in various dimensions almost automatically; with end objective to upliftment of economy, education, healthcare, safety, lifestyle etc. and eventually to help rural society as part of a Digital India.

Proposed work:
The proposed work leading to development of the ideal ecosystem requires an implementation of homogeneous ICT infrastructure to provide access to data and services through pervasive devices like smart mobile phones, smart sensors, and smart framework. The citizens can get all variety of services as well as can easily control & monitor processes and devices. Design and Smart framework and smart sensors with generic protocol and interfaces are the key challenges. These will provide better safety, lifestyle, resource and energy management.
According to Cisco, IMB etc., more than 1 million devices are connected to Internet. Till today, due to limited number of devices connected to Internet, the need for middleware, embedded on Linux OS, which was not prominently there, but as number of IoT Devices increases requirement of standardization as well as middleware has increased.

The proposed middleware with following context will provide strong backbone and complete Eco cycle for a smart village:

1. Kernel which can connect different IoT devices operating on different protocols.
2. Modern applications layer like smart mobile phones which allows installations of third party applications.
3. Middleware developed on open source software resides on local HUB and interacts with shell and mobile devices.
4. Shell layer of OS resides on cloud, and does the computational work.

The Framework can be used to form a complete eco-system integrating people, process and devices. This can help to realize smart city, smart village and smart cluster etc. which helps to implement & invent on modular based framework creating the values for smart villages with complete ecosystem.

Smart Sensors
Numerous electronic devices generate huge amount of data, which are of immense importance and can be used for more than one purpose and more than one occasions at more than one locations. At present, they are in isolation and do not follow systematic protocol nor they are communicative with 'world'. These may be safety sensors at home, devices for healthcare, soil sensors, cattle tags, health bands, energy monitoring &

distribution control devices, climatic sensors, CCTV systems, entertainment systems like TV, Music system, home theatre, Lights, ACs, Fans, and many more. The present devices are operating at their respective locations. The data/ log generated are not stored in a central data repository because of lack of network integration and communication capabilities. If a proper framework satisfies this need/requirement, is expected to facilitate data to be stored in a database as well as processing of stored data to activate certain critical processes by issuing commands. This implementation will not only automate but it will be intelligent/ smart system. The proposed framework and smart sensors developed satisfies the stated need/requirements to implement smart system. The prototype provides a flexibility of developing services to be embedded to the installed middleware by simply writing a script, which is added to the library of the services. This is an innovative feature of the middleware.
The IoT enables the possibility of information discovery about a tagged object or a tagged person by browsing an internet address or database entry that corresponds to a particular active device with sensing/ actuating capability. It is a media for information exchange between the physical world to a digital/cyber world. With available wireless communication, the wireless node entities can increase their effective usage with virtue of big data, extensive analytics and informatics.

Proposed indigenous smart sensors shall 'talk' to cloud with a very generic protocol. Smart sensors form a WSN (Wireless Sensor Network) using wireless links like RF, WiFi, IR, Bluetooth, which are compatible with devices like TV, air conditioners, lights, fan, safety sensors, curtains, pumps, and other appliances; while, the cloud connectivity is achieved through smart hub. These sensors and actuators will be/are Internet compatible.

This requires device connectivity through a single hardware hub which integrates all the devices, get status of the devices also receive data from various implanted wireless sensors in the integrated network. The received data from the sensors is processed by processors in the hub and the scripts activating the services comes into action to automate the process, control the process and devices and provides intended services to the end users of the system.

Methodology
Figure-1 shows the architecture of the system topology. Server on the cloud is the heart of the system where computational work and datamining is done. Besides managing the devices, the proposed framework supports augmented reality, artificial intelligence, housekeeping and administrative support.
At individual home or office, TV screen is connected with smart Hub which links cloud, mobile devices, access points and devices virtually. The devices are configured and managed through Hub, while user interactions are done through air mouse via TV or mobile devices. The end devices (like smart sensors, lights, fans, curtains, doors, electrical gadgets etc.) are controlled through user commands, cloud events or personal profiles.

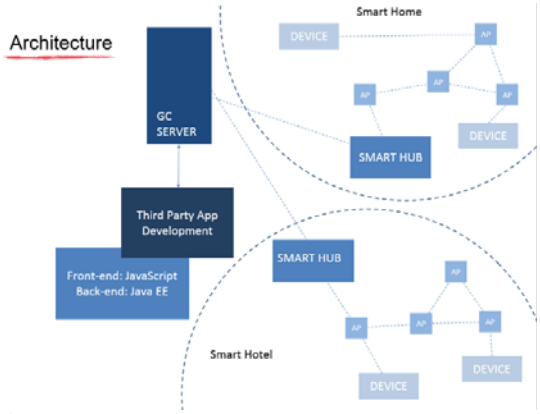

Figure-1

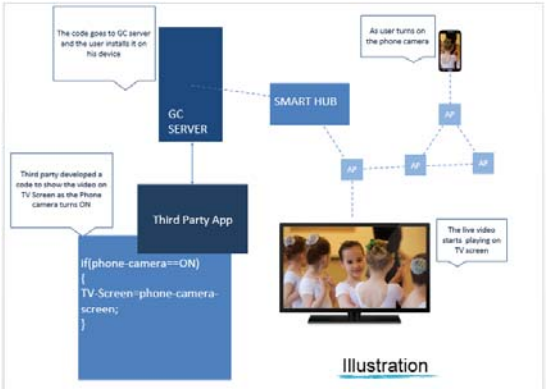

Figure-2

As shown in Figure-2, devices communicate through access points (AP). The APs are connected to HUB via WiFi and uses RF, Bluetooth, IR etc for connectivity with devices. While configuring new devices, the unknown (which is not in the local device library) 'remotes' are taught through APs.
The example of third party Apps is also highlighted in Figure-2. The simple script can be written by any individual to create 'profile' of the choice, which can be shared to other users seamlessly.

Conclusion

A complete study of village ecosystems has been done and reviewed meticulously to understand the requirements and needs of people and society for integration of smart sensor technology and framework to become part of their routine life.

The IoT based smart sensor technology can be implemented for various utilities in village to make digitally smart villages in education, healthcare, agriculture & farming, transport, e-governance, craft, local art etc. to realise better life and economic reforms for villages.

The proposed work is implemented as smart home in which all the devices are connected and control lighting, fans, window curtains for their switching ON/OFF through TV, mobile devices, or through profiles. This implantation serves as template for building smart hospital, smart schooling system, smart governance, and eventually, to form a smart village ecosystem.

RURBANISATION OF INDIA
The Slow Change of Rural India, and ICT's Role and Opportunities

Bipin Pradeep Kumar, Gaia Smart Cities.

Abstract: *India has traditionally been a country of villages. Urban India had been but a shadow of its rural counterpart. But this is changing since late. There has been a slow transition under play in this traditional setting, and a more accelerated one expected. This transition brings with it its own needs and challenges in areas like public services, housing, basic utilities, marketplaces, education, health and infrastructure; services that allow societies to function and even thrive. Bringing to fore the slow upheaval and its possible impact, the role played by ICT and the new services required in this transforming landscape are areas addressed (using 2 cases of ICT in rural Karnataka as examples) in this paper.*

1. Introduction

Rurbanisation by its very approach and feature is a phenomenon that presents its effect on rural patterns. In its earliest recorded versions – Kayser, 1990[1] and Mahajan, 2010[2] it is defined as: "a process of altering rural forms with pre-selected urban patterns and lifestyles, which creates new genetically altered rurban forms". It has been adapted more recently by the Indian government as 'Villages with a rural soul but an urban feel with all urban amenities'[3]. Nonetheless, rurbanisation is a process of rural change.

The 2011 census of India classifies all places with a municipality, corporation or cantonment board and a notified town area committee, etc. as an urban unit, Town or Statutory Town. All other units of living that satisfy the following criteria are classified as Census Towns: a minimum population of 5,000; at least 75% of the male workers engaged in non-agricultural pursuits; and a minimum density of 400 people/sq. km. As such, there are 7,935 Towns, 4041 Statutory Towns and 3894 Census Towns in India[4]. All other areas that are not categorized as urban are considered as rural, of which it lists 6,40,867 villages in India

On one hand it is within this arena of urban and rural India that there is the migration from rural to urban and expansion and growth of new urban agglomerations, just as there is the evolution of rural India itself. On the other hand, there is the transformation led by the explosion of Information and Communication Technologies (ICT) and its associated services. ICT is changing the way India – both rural and urban works, socializes, lives and even draws its aspirations from and this affects rural India too. This transition and transformation, and what it can facilitate in the form of new services, more transparent operations, easier access to healthcare and education, an open democracy, visible environmental impacts, effective and productive labour and social inclusion have the potential to enable Indians to live a better quality of life.

The first section deals with the transition arena, the changes that are happening to rural India. With the figures and facts from secondary studies presented, it provides a different lens to look through and highlights the impact. The subsequent section deals with the transformational power of ICT, through networks of communication and information in rural and semi urban India and its importance. The last section, through primary research deals with a few ICT solutions in use by this new rurban populace.

2. Rurban transition

With change as the underlying theme, we can classify the urban-rural shift underplay into three broad areas -

[1] Kayser B. The rural renaissance. Sociology of campaigns in the western world. Armand Colin, Paris, 1990
[2] http://sdmahajan.tripod.com/rurbanization.htm
[3] http://vibrantgujarat.com/Portal/Event_Images/Attachment/79/3_1_Panel-Discussion-Rurbanization.pdf
[4] http://www.censusindia.gov.in/2011-prov-results/paper2/data_files/india/Rural_Urban_2011.pdf

the migration to and growth of new urban agglomerations, the evolution of rural India and the rise in Semi Urban India. Though the migration cannot strictly be called rurbanisation, it is a large rural change with considerable momentum. Combining this with the simple fact that there will be rural populace in a new urban environment, there could be large swathes of people requiring ICT solutions and services tailored to their needs. Similarly the change within rural India itself merits its own needs and solutions, just as the rise in semi urban India merits its own. The sections below illustrate why these are segments we need to address:

Migration to and growth of Urban India:

In 2011 India had a population of 68.84% living in rural India and the remaining 31.16% living in an urban setting. This is expected to reduce to 60% in villages with urbanization at 40% in 2030. Though, in some states like Karnataka, the averages are already different with urban population in 2011 estimated at 38% and the balance 62% in rural areas[5].

The population of India is expected to be 1470 million in 2030; an increase of almost 210 million in urban, and 48 million in its rural areas. The increase of 210 million people could be a combination of migration and organic growth. What isn't obvious in this same vein and probably disturbing to the burgeoning urban populace is the migration path.

Typically migration occurs to the top ten cities of India. These are Mumbai, Delhi, Bengaluru, Hyderabad, Chennai, Kolkata, Ahmedabad, Pune, Surat and Jaipur[6]. These top 10 cities, just 0.1% of India's land mass in 2011 had 8% of India's population and contributed about 15% of the GDP[7]. There is an absence of reliable disaggregated growth data for all these cities, but if we were to distribute a major portion of the 210 million among these 10, in sheer number terms, it would be an understatement to call it challenging. Even if we were to distribute a major portion of 210 million among the top 100 cities of India keeping the current population as a factor it would still imply most major cities doubling in size or growing by almost 50%. This increase puts a significant strain on the already constrained and limited resources and infrastructure.

At a national level it is a 35.9% increase in urban populace, but a meager 5.8% increase in the rural populace. This would affect various national needs such as access to water supply, sanitation, urban sprawl and a strain on institutional framework among others, not just bringing a myriad set of challenges nationally.

Evolution of Rural India

Traditionally, agriculture played a vital role in India's economy. But this is slowly beginning to change. While the migration numbers in the earlier section underline a geographic shift of people, the activities and data from present rural India cast a different view of the village ecosystem of today's India. At Independence, agriculture contributed about 60% of our GDP, but it is barely 14% now[8]. Not just as an overall factor, Agriculture as a contributor to rural income has been declining steadily from about 43% in 2000 to about 27% (estimates) in 2012. This could be attributed to the higher growth in other sectors, but it depicts the evolution of rural India to other forms of livelihood.

At the same time, 75% of all factories in India between 1999 and 2009 came up in rural India, with manufacturing creating 70% of the jobs there. This is not surprising given that there is little physical space available in cities and most factories are set up in the outskirts of cities, which are classified as rural areas

As villages start urbanising, their consumption habits change as well. In a separate study, it was stated that the rural consumption basket of 2010 in India was surprisingly similar to the urban basket of 1994. The fastest growing consumption items are durables, education and services—hitherto considered 'urban' consumption categories[9]

Rise in Semi Urban

There is a clear differentiation of India into rural and urban made by the Census 2011, but little to no literature on what constitutes semi-urban India. The Reserve Bank of India attempts to categorise semi-urban as regions with population of 10,000 and above upto 1,00,000[10] which according to the Census of India is a town and therefore urban. The UN has semi-urban as part of what constitutes a City-Region. It defines a City-Region as an urban development on a massive scale: a major city that expands beyond administrative boundaries to "engulf small cities, towns and semi-urban and rural hinterlands, sometimes expanding sufficiently to merge with other cities, forming large conurbations that eventually become city-regions." [11] This area of coverage could extend to 200 km beyond city limits. There are semi-urban pockets in large cities, but these are more a social construct than a region separate and different from the city itself.

Independent data puts the total number of semi urban households at 153 million in 2009-10, up from 135 million in 2001-02[12]. Assuming an average household of 3 people per household, it takes on massive proportions of about 459 million people. Further assuming this is growing at the same rate of 1.25% as the current (2015) population growth rate of India and if we were to consider it as steady, it translates to 198 million semi-urban households by 2030 thereby amounting to a semi-urban population of about 594 million by 2030.

One can draw different conjectures on the distribution and size of this segment, but this is beyond the scope of this document. It is sufficient to note that this requires deep analysis and insight and that we need to catalyse and facilitate the linkages of ICT solutions with semi urban users too. It will have its own challenges in water and power utilization, environmental impacts, effective and productive labour management, social inclusion, education and healthcare among others, and consequently opportunities for relevant solutions. The emerging economic importance of semi-urban India as well as their demographic presence is to be reckoned with.

3. Technology aided Transformation

The foundations of ICT are tied to Internet availability and mobile telephony. There is a need to harness the innate capabilities of the poor and complement them with capacities (information, knowledge, skills, tools, finance and collectivization) to deal with the rapidly changing external world.

The National Optic Fiber Network (NOFN) an initiative under Bharat Broadband Networks Ltd. aims to provide 100 Mbps Broadband connectivity to 2,50,000 Gram Panchayats(GPs) in the country[13]. This would ensure broadband connectivity with adequate bandwidth necessary for all kinds of use. Together with mobile telephony that telecom service companies provide, rural India will have access to video, data and Internet services in areas such as education, business, entertainment, environment, health households, e-governance services along with a plethora of government schemes. With this there is a path for rural India to achieve increased access to their rights, entitlements and public services.

The number of telephone subscribers in India at the end of Aug 2015 was 1,014.70 million. Urban subscription was 591.52 million and rural subscription at 423.18 million with an overall Tele-density at 80.44. Of this wireless (mobile) subscriber base stood at 988.69 million Mobile users in urban areas was 570.33 million and in rural areas 418.36 million[14]. Wireless tele-density in urban and rural, the former was at 145.67 and the latter at 48.09 in the month of Aug-15.

Several studies have investigated the relationship between increase in Internet penetration and mobile telephony on economic growth. In 2005 study, the London Business School found that an extra ten mobile phones per 100 people in a typical developing country

added 0.6 percentage points of growth in GDP per person[15]. In another, Deloitte research cites a World Bank study that shows that in developing economies a 10% increase in broadband penetration increases per capita GDP growth by 1.3%.[16]

ICT benefits and advancements are not limited to agriculture. Access to a new breed of electronics, mobile and Internet based services extend the range of business services and livelihood opportunities to rural communities. The mobile phone and the connectivity it provides is slowly becoming a means of accessing information and controlling systems, not just as a tool for communication. New services and approaches as illustrated below are arising that place the mobile as a crucial element in rural development. It aids in services, and building assets and skills such that people in rural areas can avail new opportunities for their personal enhancement, income generation and employment.

4. New ICT services in rurban India

We explore 2 novel cases of how ICT has been used in Kangandlahalli village in KGF, Kolar district, Karnataka, around 100 Km from Bengaluru. In these cases, ICT is not about having a computer, or integration with the State Wide Area Network (SWAN) or e-Governance solutions. Computers help, but these solutions are more about having a mobile phone, connectivity and some electronics. These cases also illustrate that it is not just simple agricultural solutions like weather or commodity prices in nearest markets that are sought by rural India, but that the today's rural India has a certain technological maturity and seeks a truly evolved set of new services and solutions. Similarly, solutions are not dependent on language or literacy levels, they are agnostic to both. They are supplementary to their livelihood and are looked upon as new tools, mostly oblivious to the technological complexity underneath. Most require an Internet connection and these are solutions that its urban counterparts will identify with.

Case 1: Poultry

The first one is in a fairly sized poultry that houses around 6000 birds for fertilised egg collection. Unlike a regular poultry, here the focus in on the eggs that are sold to other poultries for rearing birds. There is currently a daily output of 4000 egg, with each egg being sold for between Rs. 12 to Rs. 14. Eggs are retrieved every day and sorted, graded, packed and transported directly to their customers.

Case 1: ICT expectations

The owners are exploring video surveillance (with rudimentary video analytics). This is being considered to prevent theft and misuse of the resources and facilities. There is a need to monitor temperature regularly which is done manually at periodic intervals presently. With the aid of local students, the owners are trialing a system to automate temperature and humidity, using sensors connected to a GSM device. This sends notifications over SMS and triggers alarms in the event of anomalies, further progressing to a feature that can activate a water spray remotely for bringing the temperature down using a missed call. Also under consideration is automating water spray and feed dispensing to reduce labour costs and also reduce manpower which is increasingly becoming a scarce resource.

To summarise these in ICT terms, they are: 1) Video Surveillance with Video Analytics, 2) Remote Asset Monitoring, 3) Remote Control of Systems or Remote Asset Management. 4) Robotics or Systems Automation and 5) Temperature and Humidity sensors.

Case 2: Milk Cooperative

With an annual output of 138 MT, India is the largest producer of milk in the world[17]. More farmers are seeking other means of livelihood cause of scarcity of water, economic benefits and leveraging innovative government programs. In this village, several have procured cows with loans and subsidies provided by the government. On average each cow produces about 15-20 liters/day. This is sold for a price of Rs.20/liter, in addition to which they receive Rs.4/liter as Govt. subsidy. Typically livestock owners with 5 cows make an

[17] http://www.ibef.org/blogs/india-the-largest-milk-producer-in-the-world

avg. of Rs. 15000 to 20000 every 2 weeks which is the duration of payment. There are incidents like 'Foot & mouth disease' that have caused many cows to perish, but backed by robust insurance schemes by the state, most have received insurance amount of Rs. 40K/cow. These are sometimes misused.

Case 2: ICT expectations

Small farmers are encouraged to come to the milk cooperative to use the milking facilities there, while larger ones use their own hand operated or electro-mechanical (diesel or diesel + electric) milking machines. These are preferred over hand milking as it prevents infection caused by additives used for frictionless manual process. Past experiences with diseases have taught them the benefits of machines. These machines are in the range of Rs. 10000 to Rs. 65000 and diesel ones consume only 200ml of diesel in 1 hour while pumping milk at the rate of 12ltrs/3minutes.

At the milk cooperative there is an ordinary or electronic lactometer to measure the specific gravity of buffalo and cow milk to detect contaminants. There is also an electronic butyrometer used to measure the density of milk, or the fat content in milk. While it is not a practice now, there is growing consent among livestock owners to the milk cooperatives to offer a differential fat content linked price. In this manner, livestock owners who provide better care, good feed and practice sustainable methods benefit more. Livestock owners also prefer money transfer directly into their bank accounts to prevent middleman charges and to obtain it in time. Livestock owners also request their daily supply quantity to be sent their mobile phone.

At the co-operatives end, they are tied to government insurance schemes or private insurance and banks. These institutions choose to be updated of their customers credit history, loan repayment and premium payment as well as facilitate easier methods to undertake these.

To summarize these in ICT terms, they are: 1) Electro-mechanical Systems, 2) Density and other sensors, 3) Financial services and 5) Insurance Services

5. Perspectives and Conclusion

- The massive migration to urban centers should be stemmed as it could be fraught with catastrophic consequences.
- If left unchecked the urban and semi urban population in and around the 100 or more cities will be equal or roughly equal to the population of the rest of India
- Rural India is not agriculture based anymore. Non-farm based livelihoods are making its presence felt
- Access to a new breed of electronics, mobile and Internet based services extend the range of business services and livelihood opportunities. ICT needs are not limited to agriculture.
- Rural ICT is not about having a computer, or access to state sponsored e-Governance solutions. A mobile phone, phablet or tablet have replaced large chunky computers as means of information, communication and entertainment
- The integration of electronics with computing systems and their proliferation have significant benefits in Rural India
- Literacy or language is not a barrier to benefitting from integrated electronic and computing services.

6. Acknowledgements

I'd like to express my gratitude to Mayur Dave for giving me the opportunity to write this, Shilpi Batra from M2Mpaper for igniting my thoughts on Smart villages and then keeping me engaged in the Village ecosystem, Naveen Ram of Kangandlahalli for the work he has done in his village and showing us how villages have evolved, and to Aastha Sayal for proof reading this.
